The genus *Kluyvera* contains five closely related species: *K. ascorbata*, *K. cryocrescens*, *K. georgiana*, *K. intermedia*, and *K. sichuanensis*. *K. intermedia* was formerly classified as *Enterobacter intermedius*. *Kluyvera* spp. have been found in respiratory, urine, CSF, and blood cultures. Most strains are nonpigmented, but occasional isolates may produce a red-dish-blue or violet pigment. All species resemble *E. coli* colonies growing on MAC agar. Fig. 19.4 illustrates the colony characteristics of *Kluyvera* spp. Cephalothin and carbenicillin disk susceptibility tests can separate the two species *K. cryocrescens* and *K. ascorbata*. *K. cryocrescens* shows large zones of inhibition, and *K. ascorbata* has small zones. In addition, *K. ascorbata* does not ferment glucose at 5° C, whereas *K. cryocrescens* ferments glucose at this temperature.

Plesiomonas

Because of phenotypic characteristics, the genus *Plesiomonas* was formerly in the family Vibrionaceae. Like the vibrios and aeromonads, these organisms are oxidase-positive, glucose-fermenting, facultatively anaerobic, gram-negative bacilli. However, *Plesiomonas* was moved to the family Enterobacteriaceae because phylogenetic studies revealed a closer relatedness to members of that family. Unlike the Enterobacterales, *Plesiomonas* does not have the ability to produce gas from glucose, it is the only oxidase-positive member, and it is susceptible to the compound O/129. *P. shigelloides* is the only species in this genus.

Plesiomonads are straight, gram-negative bacilli that occur singly, in pairs, or in short chains or filamentous forms. They do not form capsules and are motile by monotrichous or two to five lophotrichous flagella. The genera *Plesiomonas* and *Shigella* share biochemical and antigenic features, and plesiomonads often cross-agglutinate with *Shigella sonnei*, *S. dysenteriae*, and even *S. boydii* antisera, hence the species name *shigelloides*. However, *P. shigelloides* possess a much lower virulence potential than *Shigella*, with a low symptomatic carriage rate among humans. *Plesiomonas* can be serotyped by somatic O antigens and their flagellar H antigen. Some of the numerous serotypes are ubiquitous, and others are confined to certain regions only.

P. shigelloides is found in soil and aquatic environments, but because of intolerance to increased NaCl and a minimum growth temperature of 8° C, isolates are generally found only in the fresh and estuarine waters of tropical and subtropical climates. They are widely distributed among warm- and cold-blooded animals, including dogs, cats, pigs, vultures, snakes, lizards, fish, newts, and shellfish.

P. shigelloides has emerged as a potential cause of gastroenteritis in humans, most often after the consumption of undercooked seafood, in particular shellfish, or untreated water. At least three major clinical types of gastroenteritis are caused by *Plesiomonas*:

- The more common watery or secretory diarrhea
- A subacute or chronic disease that lasts from 14 days to 2 to 3 months
- A more invasive, dysenteric form that resembles colitis

Fig. 19.4 A, Blue-violet pigment of *Kluyvera* spp. growing on sheep blood agar. This *Kluyvera* species resembles the colony morphology of *Escherichia coli* growing on MacConkey (MAC) agar. B, Appearance of *K. cryocrescens* growing on MAC agar. C, Appearance of *K. ascorbata* growing on MAC agar.

On average, 25% to 40% of symptomatic patients present with fever, vomiting, or both, and the single most common clinical symptom for all such patients is abdominal pain. Most cases are self-limiting, but antimicrobial therapy is indicated in severe and prolonged cases. Reports of *P. shigelloides* infection in patients with HIV infections are increasing, as are associations with inflammatory bowel disease.

Plesiomonads have also been isolated from several extraintestinal infections, most notably meningitis in neonates, septicemia, shock, and wounds. Occupational exposure can be a source of infections for veterinarians, zookeepers, aquaculturists, fish handlers, and athletes participating in water-related sports. More serious infections, such as bacteremia and meningitis, usually occur only in severely immunocompromised patients or neonates. Reports include cases of continuous ambulatory, peritoneal dialysis–associated peritonitis. Furthermore, biliary tract disease has been identified as a possible risk factor for bacteremia. Cases are possibly underreported because of the similarity to *E. coli* grown on most ordinary enteric media.

Antimicrobial therapy is indicated for patients with severe or chronic disease. Similarly, extraintestinal infections, particularly among neonates, often require antimicrobial therapy. Studies have shown a general resistance to the penicillin class of antibiotics, but penicillins combined with a β -lactamase inhibitor, as well as trimethoprim-sulfamethoxazole, are active. There have been reports of resistance to more than one aminoglycoside (e.g., gentamicin, tobramycin, amikacin), but the quinolones, azithromycin, cephalosporins, and carbapenems appear to be effective therapy.

Erwiniaceae

Pantoea

Pantoea is a diverse group of about two dozen species of yellow-pigmented organisms containing many plant pathogens. Some current members of the genus *Pantoea* were previously classified in the genus *Erwinia*. Current members of the genus *Erwinia* are environmental isolates and potential plant pathogens rarely recovered in human specimens. However, several strains have been isolated from clinical specimens including blood, CSF, sputum, and urine. *Pantoea agglomerans* gained notoriety with a nationwide outbreak of septicemia resulting from contaminated intravenous fluids. Originally designated as *Enterobacter agglomerans* complex, it includes lysine-, ornithine-, and arginine-negative or “triple decarboxylase-negative” members. Fig. 19.5 depicts a yellow-pigmented *P. agglomerans*.

Morganellaceae

Proteus

The genera *Proteus*, *Morganella*, and *Providencia* belong to the family Morganellaceae. They are widely disseminated in the environment, are normal intestinal microbiota, and are recognized as opportunistic pathogens. *Proteus mirabilis* is the most common clinical isolate. The family is distinguished from the other members of the Enterobacterales by their ability to deaminate the amino acid phenylalanine. Virtually no other members of the Enterobacterales synthesize the required enzyme, phenylalanine deaminase. None of the members of this family ferment lactose.

The genus *Proteus* consists of at least 13 species. *P. mirabilis* and *P. vulgaris* are widely recognized human pathogens, with *P. mirabilis* being the more common isolate. Both species have been isolated from urine, wounds, and ear and bacteremic infections. *Proteus* spp. are responsible for 3% of all healthcare-associated infections in the United States, particularly UTIs. They ascend the urinary tract, causing infections in both the lower and upper urinary tract. They can infect the proximal kidney tubules and can cause acute glomerulonephritis, particularly in patients with urinary tract defects or catheterization. The urease activity of *P. mirabilis* results in an increased urine pH and can lead to struvite kidney stones (calculi).

P. mirabilis and *P. vulgaris* are easily identified in the clinical laboratory because of their characteristic colony morphology. Both species, particularly *P. mirabilis*, can produce “swarming” colonies on nonselective media, such as SBA (Fig. 19.6). The swarming characteristic is a result of a tightly regulated cycle

Fig. 19.5 Yellow-pigmented *Pantoea agglomerans* on sheep blood agar. (Courtesy Jean Barnishan.)

Fig. 19.6 Example of *Proteus mirabilis* swarming on sheep blood agar. (Courtesy Kimberly Walker and R. Abe Baalness.)

of differentiation from standard vegetative cells (swimmers) to hyperflagellated, elongated, polyploid cells (swarmers) capable of coordinated surface movement. Swarmer cells also produce the distinct odor associated with *Proteus* colonies, sometimes described as “burnt chocolate,” and are thought to play a role in the ascending nature of *Proteus*-associated UTIs.

Both species hydrolyze urea and produce H_2S , although some strains of *P. vulgaris* are negative for H_2S . *P. mirabilis* is differentiated from *P. vulgaris* by the indole and ornithine decarboxylase tests. *P. mirabilis* does not produce indole from tryptophan and is ornithine-positive, whereas *P. vulgaris* produces indole and is ornithine-negative. *P. vulgaris* ferments sucrose and gives an acid/acid reaction in triple sugar iron (TSI) agar. *P. penneri* can also swarm on nonselective media. *P. penneri* has been isolated from patients with diarrhea and UTIs, although the organism’s role in diarrheal disease has not been proven.

Morganella

The genus *Morganella* comprises one species of medical importance, *M. morganii*, with two subspecies, *M. morganii* subsp. *morganii* and *M. morganii* subsp. *sibonii*. Although not a common isolate, it is an important opportunistic pathogen because of its multidrug resistance and increased virulence. *M. morganii*, a recognized healthcare-associated pathogen, has been primarily identified as a cause of UTIs and occasionally wound infections and bacteremia. *M. morganii* subsp. *morganii* is differentiated from *M. morganii* subsp. *sibonii* by its inability to ferment trehalose. Most *M. morganii* subsp. *sibonii* are motile but do not swarm. Key identifying characteristics are listed in Table 19.7.

Providencia

The genus *Providencia* contains four clinically notable species: *P. alcalifaciens*, *P. stuartii*, *P. rettgeri*, and *P. rustigianii*. *P. rettgeri* is a documented pathogen of the urinary tract and has caused occasional outbreaks in health care settings. It has also been implicated in diarrheal disease among travelers. Similarly, *P. stuartii* has been implicated in outbreaks in burn units and has been isolated from urine cultures. Infections caused by *P. stuartii* and *P. rettgeri*, especially in immunocompromised patients, are particularly difficult to treat because of their resistance to antimicrobials. Studies of the epidemiology of *P. alcalifaciens* support its role in traveler’s diarrhea; however, its pathogenicity is not well understood. *P. rustigianii* is rarely isolated, and its pathogenicity also remains unproven. See Table 19.7 for the differentiating characteristics of medically important *Proteus*, *Providencia*, and *Morganella*.

Hafniaceae

Hafnia

The genus *Hafnia* is composed of three species: *H. alvei*, *H. paralvei*, and *H. psychrotolerans*. *Hafnia* spp. have been isolated from many anatomic sites in humans, animals, and in the environment. They can produce a verocytotoxin, although *H. alvei* is more likely to be toxigenic, and have been linked to gastroenteritis and are occasionally isolated in stool cultures. The species are differentiated based on malonate utilization, salicin and D-arabinose fermentation, and on β -glucosidase activity. A delayed positive citrate reaction is a major characteristic of *Hafnia*.

Modified from Washington, J. (1981). *Laboratory procedures in clinical microbiology* (2nd ed.). New York: Springer-Verlag.

Edwardsiella

The genus *Edwardsiella* is composed of five species: *E. tarda*, *E. anguillarum*, *E. hoshinae*, *E. ictaluri*, and *E. piscicida*. *E. tarda* is the only recognized human pathogen. *E. tarda* is an opportunist, causing bacteremia, GI infections, and wound infections. It is reported to have a significant mortality rate. Patients with underlying hepatobiliary disease are at increased risk of infection. Members of this genus are negative for urea and positive for lysine decarboxylase, H_2S , and indole and do not grow on Simmons citrate.

Serratia

The genus *Serratia* is placed within the family Yersiniaceae, which also includes the genus *Yersinia*, considered a primary pathogen and is discussed later in the chapter. The genus *Serratia* comprises a diverse group of organisms with at least 25 named species. *Serratia* spp., widespread in the environment, are opportunistic pathogens isolated from outbreaks in health care settings. *S. marcescens*, *S. rubidaea*, and *S. plymuthica* are noted for producing a characteristic pink-to-red pigment, prodigiosin, especially when the cultures are incubated at room temperature. Pigment production is typically a characteristic in those strains of environmental origin. Fig. 19.7 illustrates the pigmentation of *S. marcescens* and *S. rubidaea*.

Clinically, *S. marcescens* is considered the most significant species, and many clinical isolates are nonpigmented. It has been found frequently in healthcare-associated infections of the urinary or respiratory tract and in bacteremic outbreaks in nurseries and cardiac surgery and burn units. Contamination of antiseptic solution used for joint injections resulted in an epidemic of septic arthritis. Ophthalmic infections caused by *S. marcescens* have also been reported.

S. odorifera, as the species name implies, emits a dirty, musty odor resembling that of rotten potatoes. It is isolated predominantly from sputum, blood, and urine. *S. liquefaciens*, *S. rubidaea*, *S. ficaria*, *S. fonticola*, and *S. quinivorans* have also been isolated from human sources.

Generally, *Serratia* spp. ferment lactose slowly and are positive for the ONPG test. They are differentiated from other members of the order by their ability to produce extracellular DNase. Like the *Klebsiella* and *Enterobacter* species, *Serratia* spp. are typically VP positive. *Serratia* spp. are also known for their resistance to a wide range of antimicrobials.

Susceptibility tests must be performed on each isolate to determine appropriate antimicrobial therapy.

Primary pathogens in the order Enterobacterales

Salmonella and *Shigella* are members of the family Enterobacteriaceae. These organisms produce GI illnesses in humans, and neither is considered normal biota of the human intestinal tract. *Salmonella* spp. can inhabit the GI tract of animals. Humans acquire the infection by ingesting the organisms in contaminated animal food products or insufficiently cooked poultry, milk, eggs, and dairy products. Animal reservoirs include poultry and rodents. Some *Salmonella* infections are transmitted by human carriers.

Infections caused by *Shigella* spp. are associated with human carriers responsible for spreading the disease; no animal reservoir has been identified. *Shigella* dysentery usually indicates improper sanitary conditions and poor personal hygiene. Infections caused by *Yersinia* spp., members of the family Yersiniaceae, are transmitted by a wide variety of wild and domestic animals. *Yersinia* infections include GI disease, mediastinal lymphadenitis, fulminant septicemia, and pneumonia.

Salmonella

Members of the genus *Salmonella* produce significant infections in humans and in certain animals. Other *Salmonella* serotypes are typically found in cold-blooded animals as well as in rodents and birds, which serve as their natural hosts. Annually, the CDC reports several outbreaks of human salmonellosis acquired from turtles and poultry. Salmonellae are gram-negative, facultatively anaerobic bacilli that morphologically resemble other enteric bacteria. On selective and differential media used primarily to isolate enteric pathogens (e.g., MAC), salmonellae produce clear, colorless, nonlactose-fermenting colonies; colonies with black centers are seen if the media (e.g., HE or XLD) contain indicators for H_2S production. The biochemical features for the genus include:

- Almost every isolate does not ferment lactose.
- Test results for indole, phenylalanine deaminase, urease, and the Voges-Proskauer test are negative.

Fig. 19.7 **A**, *Serratia marcescens* growing on chocolate agar (left) and showing brick-red pigment when grown on MacConkey (MAC) agar (right). **B**, Pinkish red pigmentation of *Serratia rubidaea* growing on MAC agar.

- Most isolates produce H_2S ; a major exception is *Salmonella* Paratyphi A, which does not produce H_2S .
- They do not grow in media containing KCN.

Classification

Currently, based on DNA homology and sequencing, the genus *Salmonella* comprises only two species. *S. enterica* is the type species of the genus and accounts for almost all human infections. *S. bongori* is a rarely isolated species that is named after the town of Bongor in Chad, Africa. It was initially isolated in 1966 from a lizard and is usually isolated from cold-blooded animals and the environment.

Within the species *S. enterica* are six subspecies: *S. enterica* subsp. *enterica* (subspecies I), *S. enterica* subsp. *salamae* (subspecies II), *S. enterica* subsp. *arizonae* (subspecies IIIa), *S. enterica* subsp. *diarizonae* (subspecies IIIb), *S. enterica* subsp. *houtenae* (subspecies IV), and *S. enterica* subsp. *indica* (subspecies VI). Nearly all former *Salmonella* spp. have been placed as serotypes below the level of *S. enterica* subsp. *enterica* (e.g., *S. enterica* subsp. *enterica* serotype Typhi), which is often more simply written as *Salmonella* Typhi (serotype is capitalized and not italicized). Currently, greater than 2500 serotypes are recognized, but fewer than 100 are associated with human infections. Table 19.8 shows the characteristic features of *Salmonella* serotype Typhi, *Salmonella* serotype Choleraesuis, and *Salmonella* serotype Paratyphi. Members of the former genus *Arizona*, now subspecies IIIa of *S. enterica*, are found in infections with symptoms identical to those of *Salmonella* infections and may be transmitted to humans from pet turtles, snakes, and fish.

Virulence factors

Factors responsible for the virulence of salmonellae include capsule production and fimbriae used in adherence in initiating intestinal infection. Other factors that contribute to the virulence of salmonellae is their ability to traverse intestinal mucosa and survive inside host cells. Also, enterotoxins produced by certain *Salmonella* strains that cause gastroenteritis have been implicated as a significant virulence factor.

Antigenic structures

Salmonellae possess antigens resembling antigens of other enterobacteria. The somatic O antigens and flagellar H antigens are the primary antigenic structures used in serologic grouping of salmonellae. A few strains may possess capsular (K) antigens, designated Vi antigen. The serologic identification of the Vi antigen is important in identifying *Salmonella* serotype Typhi. Fig. 19.8 shows the antigenic structures used in serologic grouping and their locations. The heat-stable O antigen of salmonellae, as is the case with other enteric bacteria, is the lipopolysaccharide located in the outer membrane of the cell wall. Many different O antigens are present among the subspecies of *Salmonella*; more than one O antigen can also be found in a particular strain. The O antigens are designated by Arabic numbers.

In contrast with the O antigens, flagellar antigen proteins are heat labile. The H antigens of salmonellae occur in one of two phases: phase 1, the specific phase, and phase 2, the nonspecific phase. Phase 1 flagellar antigens occur only in a few serotypes and determine the immunologic identity of the particular serotype. Phase 1 antigens agglutinate only with homologous antisera. Phase 2 flagellar antigens occur among several strains. Shared by numerous serotypes, phase 2 antigens react with heterologous antisera. The heat-labile Vi (from the term *virulence*) antigen is a surface polysaccharide capsular antigen found in *Salmonella* serotype Typhi and a few strains of *Salmonella* serotype Choleraesuis. The capsular antigen plays a significant role in preventing phagocytosis of the organism. The Vi antigen often blocks the O antigen during serologic typing but may be removed by heating.

Clinical infections

In humans, salmonellosis can occur in several forms:

- Acute gastroenteritis or food poisoning characterized by vomiting and diarrhea
- Typhoid fever, the most severe form of enteric fever, caused by *Salmonella* serotype Typhi, and enteric fevers caused by other *Salmonella* serotypes (e.g., *Salmonella* Paratyphi and *Salmonella* Choleraesuis)

- Nontyphoidal bacteremia and other extraintestinal complications
- Carrier state following *Salmonella* infection

Humans acquire the infection by ingesting the organisms in food, milk, and water contaminated with human or animal excreta. Except for *Salmonella* Typhi and *Salmonella* Paratyphi, salmonellae organisms infect various animals that serve as reservoirs and sources of human infections. *Salmonella* serotypes Typhi and Paratyphi have no known animal reservoirs, and infections seem to occur only in humans. Human carriers are often a source of these serotypes.

Gastroenteritis

Salmonellae are some of the most common causes of food poisoning. The CDC estimates the annual incidence of *Salmonella* infection to be 1.35 million. The *Salmonella* strains associated with gastroenteritis are usually those found in animals; most such strains in the United States are members of *S. enterica* subsp. *enterica*. The source of the infection is attributed primarily to poultry, milk, eggs, and egg products as well as to handling pets. Insufficiently cooked eggs and domestic fowl, such as chicken, turkey, and duck, are common sources of infection. More recently in the United States, there was a series of outbreaks by various *Salmonella* serotypes related to the ingestion of foodstuffs such as papayas, tahini, chicken, ground beef, eggs, turkey products, pasta salad, pre-cut melons, coconut, cereal, peaches, mushrooms, and onions. In 2015 to 2016, there were 907 cases resulting in 6 deaths linked to *Salmonella* Poona in 40 states. The outbreak was traced to cucumbers imported from Mexico and distributed to many states in the United States.

Numerous outbreaks also have been linked to calves and poultry at petting zoos. Handling live animals, such as reptiles, can also result in salmonellosis. In 2020, there was a 25-state outbreak of *Salmonella* Typhimurium associated with hedgehogs affecting 49 people. In addition, from August 2010 to June 2011, the CDC documented 109 cases of *Salmonella* Typhimurium from clinical and teaching laboratories. Infected individuals included students in microbiology teaching laboratories and employees in clinical microbiology laboratories and their household contacts.

Salmonella gastroenteritis occurs when enough organisms contaminate food that is maintained under inadequate refrigeration, allowing growth and multiplication of the organisms. The infective dose necessary to initiate the disease, approximately 10^6 bacteria, is much higher than the dose required

for shigellosis. Cooking utensils, such as knives, pans, and cutting boards used in preparing the contaminated food, can spread the bacteria to other food. Direct transmission from animal to person and from person to person in institutions has been reported.

The symptoms of intestinal salmonellosis, which may appear 8 to 36 hours after ingestion of contaminated food, include nausea, vomiting, fever and chills, diarrhea (watery or blood-tinged), and abdominal pain. Most cases of *Salmonella* gastroenteritis are self-limiting. Symptoms usually disappear within a few days, with few or no complications. Patients with sickle cell disease and other hemolytic disorders, ulcerative colitis, and malignancy seem to be more susceptible to salmonellosis. The infection can be more severe in very young children, older adults, and patients with other underlying disease. Dissemination can occasionally occur; in such cases, antimicrobial therapy is required.

The antimicrobials of choice include fluoroquinolone, azithromycin, and ceftriaxone. Nevertheless, susceptibility testing must be performed. Antimicrobial therapy is usually not indicated in uncomplicated cases. Antimicrobial therapy is believed to prolong the carrier state. Antidiarrheal agents are also restricted in cases of salmonellosis because these agents may encourage adherence and further invasion. In cases of dehydration, fluid replacement therapy may be indicated.

Enteric fevers

The clinical features of enteric fevers include:

- Prolonged fever
- Bacteremia
- Involvement of the reticuloendothelial system, particularly the liver, spleen, intestines, and mesentery
- Dissemination to multiple organs

Enteric fever caused by *Salmonella* Typhi is known as **typhoid fever**, a febrile disease that results from the ingestion of food contaminated with the organisms originating from infected individuals or carriers. *Salmonella* Typhi does not have a known animal reservoir; humans are the only known source of infection. Other enteric fevers include paratyphoid fevers, which may be caused by *Salmonella* serotypes Paratyphi A, B, and C and *Salmonella* serotype Choleraesuis. The clinical manifestations of paratyphoid fevers resemble typhoid fever but are less severe, and the fatality rate is lower.

Typhoid fever occurs more often in tropical and subtropical areas, where international travelers are more likely to acquire the infection. The highest incidences are found in Pakistan and India. Improper disposal of sewage, poor sanitation, and lack of a modern potable water system have caused outbreaks of typhoid fever when the organisms reach a water source. This situation is uncommon in the United States and other developed countries, where water is purified and treated, and handling of waste is standardized. Carriers, particularly food handlers, are important sources of infection anywhere in the world. Transmission through fomites is also possible. Laboratory workers in the microbiology laboratory have contracted typhoid fever while working with the organisms.

Typhoid fever develops approximately 7 to 14 days after ingestion of the organisms. The onset of symptoms depends on the number of organisms ingested; the larger the inoculum, the shorter the incubation period. Characteristically,

during the first week of the disease, the patient develops a sustained fever accompanied by malaise, anorexia, lethargy, myalgia, and a continuous dull frontal headache.

When the organisms are ingested, they can survive gastric acids and, on reaching the proximal end of the small intestine, they subsequently invade and penetrate the intestinal mucosa. At that time, the patient experiences constipation rather than diarrhea. The organisms gain entrance into the lymphatic system and are sustained in the mesenteric lymph nodes. They eventually reach the bloodstream and spread to the liver, spleen, and bone marrow, where they are immediately engulfed by mononuclear phagocytes. The organisms multiply intracellularly; later they are released into the bloodstream a second time. The febrile episode becomes more evident during this release of the organisms into the circulatory system. At this time, the organisms may be isolated easily from the blood. Fig. 19.9 shows the course of typhoid fever.

Without treatment, during the second and third weeks of the disease, the patient generally experiences sustained high fever with prolonged bacteremia. A maculopapular rash, described as “rose spots” (blanching, rose-colored papules), develops on the abdomen and extremities in up to 30% of cases. The organisms invade the gallbladder and Peyer patches of the bowel. They also reach the intestinal tract via the biliary tract. Involvement of biliary system sites initiates GI symptoms as the organisms reinfect the intestinal tract. The organism now exists in large numbers in the bowel and can be isolated from feces. The gallbladder becomes the foci of long-term carriage of the organism, occasionally reseeding the intestinal tract and shedding the organisms in the feces. Necrosis in the gallbladder leading to necrotizing cholecystitis and necrosis of the Peyer patches leading to hemorrhage and perforation of the bowel may occur as serious complications. Other complications that occur in typhoid fever include pneumonia, thrombophlebitis, meningitis, osteomyelitis, endocarditis, and abscesses.

Fig. 19.9 Culture and serologic diagnosis of typhoid fever. (Modified from Procop, G. W., et al. (2017). *Koneman's color atlas and textbook of diagnostic microbiology* [7th ed.]. Philadelphia: Wolters Kluwer.)

Bacteremia

Salmonella bacteremia, with and without extraintestinal foci of infection caused by nontyphoidal *Salmonella*, is characterized primarily by prolonged fever and intermittent bacteremia. Many serotypes can produce bacteremia in patients with underlying health conditions such as acquired immunodeficiency syndrome, solid tumors, hematologic malignancies, and diabetes. The serotypes most associated with bacteremia in immunocompetent individuals are Typhimurium, Paratyphi, and Choleraesuis. The infection has been observed among two different groups: (1) young children, who experience fever and gastroenteritis with brief episodes of bacteremia, and (2) adults, who experience transient bacteremia during episodes of gastroenteritis or develop symptoms of septicemia without gastroenteritis. The latter manifestations were observed among patients who had underlying illnesses, such as malignancies and liver disease. The risk of metastatic complications, commonly endocarditis, could be more severe than the bacteremia itself, even in individuals who do not have underlying diseases. Cases of septic arthritis can also occur in patients who had asymptomatic salmonellosis.

Carrier state

Individuals who recover from infection can harbor the organisms in the gallbladder, which becomes the site of chronic carriage. Such individuals excrete the organisms in their feces either continuously or intermittently; nevertheless, they become an important reservoir for susceptible persons. The carrier state may be terminated by antimicrobial therapy if gallbladder infection is not evident. Otherwise, cholecystectomy has been the only solution to the chronic state of enteric carriers.

Shigella

Based on molecular analysis, the genera *Shigella* and *Escherichia* are so closely related that they should be a single genus. However, for medical purposes and because of the useful association of the genus epithet with the distinct disease shigellosis or **bacillary dysentery**, they remain as separate genera. Both genera belong to the family Enterobacteriaceae. However, *Shigella* spp. are not members of the normal GI microbiota, and all *Shigella* spp. can cause bacillary dysentery. The genus *Shigella* is named after the Japanese microbiologist Kiyoshi Shiga, who first isolated the organism in 1896. The organism, descriptively named *Shigella dysenteriae*, causes the enteric disease bacillary dysentery. The disease is characterized by the presence of blood, mucus, and pus in the stool. Characteristics of *Shigella* spp. include:

- They are nonmotile.
- Except for certain types of *S. flexneri*, they do not produce gas from glucose.
- They do not hydrolyze urea.
- They do not produce H_2S .
- They do not decarboxylate lysine.

In contrast with *Escherichia* spp., *Shigella* spp. do not use acetate or mucate as a source of carbon. Table 19.9 shows the biochemical characteristics of *Shigella* spp. *S. sonnei* is unique in its ability to decarboxylate ornithine. Most isolates also slowly ferment lactose, producing delayed-positive lactose

Table 19.9 Biochemical and serologic differentiation of *Shigella* species

Fig. 19.10 Left, Lactose-negative appearance of *Shigella sonnei* growing on MacConkey (MAC) agar at 18 to 24 hours of incubation. Right, Lactose-positive appearance of *S. sonnei* growing on MAC agar after 48 hours of incubation.

fermentation with the formation of pink colonies on MAC agar but only after 48 hours of incubation. *S. sonnei* is positive for o-nitrophenyl- β -D-galactopyranoside (ONPG). These two key positive reactions help distinguish it from the other three species. Fig. 19.10 illustrates the growth of *S. sonnei* on MAC agar after 24 hours and 48 hours of incubation. On differential and selective media used primarily to isolate intestinal pathogens, shigellae generally appear as clear, nonlactose-fermenting colonies at 24 hours. Shigellae are fragile organisms; they are susceptible to the various effects of physical and chemical agents, such as disinfectants and high concentrations of acids and bile. Because they are susceptible to the acid pH of stool, feces suspected of containing *Shigella* organisms should be plated immediately onto laboratory media to increase recovery of the organism.

Antigenic structures

The genus consists of four biochemically similar species. *Shigella* spp. are also divided into four major O antigen serogroups (see Table 19.9). Several serotypes exist within each

species, except for *S. sonnei*, which has only one serotype. All *Shigella* spp. possess O antigens, and certain strains can possess K antigens. *Shigella* K antigens, when present, interfere with the detection of the O antigen during serologic grouping. The K antigen is heat labile and may be removed by boiling a cell suspension. The shigellae are nonmotile; therefore they lack H antigens.

Clinical infections

Shigellosis is the most important cause of bloody diarrhea worldwide. Annually, the World Health Organization estimates at least 80 million people suffer from bloody diarrhea caused by shigellosis, and it causes 700,000 deaths. Although shigellosis is endemic to many countries, about 99% of cases occur in developing countries. Most cases (about 70%) and deaths (about 60%) occur in children younger than 5 years of age. In the United States, an estimated 450,000 cases occur yearly.

Although all *Shigella* spp. can cause dysentery, species vary in epidemiology, mortality rate, and severity of disease. In the United States and Europe, *S. sonnei* is the predominant isolate followed by *S. flexneri*. In industrialized countries, including the United States, shigellosis is probably underreported because most patients are not hospitalized and usually recover from the infection without culture to identify the etiologic agent. *S. sonnei* infection is usually a short, self-limiting disease characterized by fever and watery or bloody diarrhea.

The demographics of *S. flexneri* infection have changed during recent years from a disease affecting mostly young children to one producing infections in young adults (approximately 25 years of age). This observation was made simultaneously with the recognition of gastroenteritis in men who have sex with men, in which *S. flexneri* has been the leading isolate. Persons with HIV infection are also at increased risk. Conversely, in many developing countries, *S. dysenteriae* and *S. boydii* are the most common isolates. *S. dysenteriae* type 1, a common producer of Shiga toxin, remains the most virulent species, with significant morbidity and high mortality. Reports exist of mortality rates of 5% to 10%, and perhaps even higher, resulting from *S. dysenteriae* type 1, particularly among undernourished children during epidemic outbreaks.

Humans and other large primates are the only known reservoir of *Shigella* spp. Transmission can occur by direct person-to-person contact and via the fecal-oral route, with carriers as the source. Shigellae can also be transmitted by flies, fingers, and food or water contaminated by feces from infected persons. Because of the low infective dose required to produce the disease (10 to 100 bacilli), shigellosis is highly communicable. Personal hygiene plays a major role in the transmission of *Shigella* spp., and certain groups are affected more than others. Young children in daycare centers, particularly infants younger than 1 year of age, are most susceptible. Most disturbing are the reports of multidrug-resistant *S. sonnei* outbreaks in daycare centers in several states. *Shigella* is also seen in people living in crowded and inadequate housing. Multiple *Shigella* outbreaks associated with passengers on cruise ships from various cruise lines have also been reported.

The clinical manifestations of shigellosis vary from asymptomatic to severe. The initial symptoms, marked by high fever, chills, abdominal cramps, and pain accompanied by

tenesmus, appear approximately 24 to 48 hours after ingestion of the organisms. The organisms, which originally multiply in the small intestine, move toward the colon, where they may be isolated 1 to 3 days after the infection develops. Bloody stools containing mucus and numerous leukocytes follow the watery diarrhea as the organisms invade the colonic tissues and cause an inflammatory reaction. Bacillary dysentery caused by *Shigella* spp. is marked by penetration of intestinal epithelial cells after attachment of the organisms to mucosal surfaces, local inflammation, shedding of the intestinal lining, and formation of ulcers after epithelial penetration. All *Shigella* spp. contain chromosomal genes for an enterotoxin and a cytotoxin. *S. dysenteriae* type 1 also carries the gene for Shiga toxin derived from a phage that is incorporated into the chromosome. Clinical manifestations are caused by penetration of gastric epithelial cells and production of toxins.

In dysentery caused by *S. dysenteriae* type 1, patients experience more severe symptoms. Bloody diarrhea that progresses to dysentery may appear within a few hours to a few days. Patients experience extremely painful bowel movements, which contain predominantly mucus and blood. In young children, abdominal pain is quite intense, and rectal prolapse may result from excessive straining. Severe cases of shigellosis can become life-threatening as extraintestinal complications develop. One of the most serious complications is ileus, an obstruction of the intestines, with marked abdominal dilation, possibly leading to toxic megacolon.

Although *Shigella* spp. infrequently penetrate the intestinal mucosa and disseminate to other body sites, it has been reported that 4% of severely ill hospitalized patients in Bangladesh have bacteremia caused by *S. dysenteriae* type 1. *S. flexneri* bacteremia and bacteremia resulting from other enteric organisms occur, presumably predisposed by ulcers initiated by the shigellae. Other complications of shigellosis include seizures, which may occur during any *Shigella* sp. infection. HUS is another complication among the shigellae exclusively associated with *S. dysenteriae* type 1 shigellosis, although about 80% of HUS cases in the United States are caused by EHEC. The effects of shigella toxin have been implicated as the mechanism responsible for the signs of disease, and it has been reported that the detectable toxin levels produced by *S. dysenteriae* type 1 are higher than those produced by other *Shigella* spp.

Yersinia

The genus *Yersinia*, in the family Yersiniaceae, currently consists of 25 named species; most are considered environmental isolates. Although many have been recovered from humans, only three species are considered human pathogens. *Y. pestis* is the causative agent of plague, and *Y. pseudotuberculosis* and *Y. enterocolitica* have caused sporadic cases of gastroenteritis; mesenteric lymphadenitis, especially in children; and generalized septicemic infections in immunocompromised hosts. All three species are regarded as zoonotic agents. The DNA relatedness between *Y. pestis* and *Y. pseudotuberculosis* is about 95%; however, they produce different clinical syndromes. *Y. enterocolitica* produces gastroenteritis that can mimic appendicitis. It has also been found to be the cause of diarrhea in numerous community outbreaks. The other members of the genus *Yersinia* are found in water, soil, and lower animals; isolates occasionally have been found in wounds and the urine of

humans. There is no evidence that species other than *Y. enterocolitica* cause intestinal disease. However, other *Yersinia* spp. have been isolated in up to 20% of stool samples from patients with diarrhea in the absence of other enteric pathogens.

Yersinia pestis

The causative agent of plague still exists in areas where reservoir hosts are found. The World Health Organization reported 3248 plague cases, with 584 deaths, between 2010 and 2015. In the United States, an average of 7 cases are reported annually, primarily in the southwestern region. Plague is a disease primarily of rodents. It is transmitted to humans by bites of fleas, which are its most common and effective vectors. In humans, plague can occur in three forms: the bubonic or glandular form; the septicemic form; and the pneumonic form. The bubonic form, the most common, usually results from the bite of an infected flea. Characteristic symptoms appear 2 to 6 days after infection. The symptoms include sudden onset of high fever, chills, and headache with swollen, painful regional lymph nodes known as buboes. Pneumonic plague can be a primary infection if the bacteria are inhaled, or it can be secondary to bubonic plague. This is the only form spread from person to person, and subsequent epidemic outbreaks can arise from respiratory transmission of the organisms. The septicemic form occurs when the bacteria are directly inoculated into the bloodstream without regional infection. Typical symptoms include fever, chills, shock, extreme weakness, abdominal pain, and sometimes bleeding into the skin leading to a rash. The fatality rate in pneumonic and septicemic plague is high—approaching 100%—in untreated patients.

Y. pestis is a nonmotile gram-negative, short, plump bacillus. When stained with methylene blue or Wayson stain, it shows intense staining at each end of the bacillus, referred to as *bipolar staining*, which gives it a “safety-pin” appearance. *Y. pestis* can be isolated on routine culture media. Although it grows at 37°C, its optimal growth temperature is 25° to 30°C. Further information relating its role as a potential bioterrorism agent can be found in [Chapter 30](#).

Yersinia enterocolitica

Human infections resulting from *Y. enterocolitica* have occurred worldwide, predominantly in Europe. The CDC estimates that 117,000 cases occur annually in the United States. It is the most commonly isolated species of *Yersinia*. The organism has been found in a wide variety of animals, including domestic swine, cats, and dogs. The role of pigs as a natural reservoir has been greatly emphasized in Europe. Other animal reservoirs have also been identified, and cultures from environmental reservoirs, such as water from streams, have yielded the organism.

Human infections can occur from contact with household pets; by the fecal-oral route; and after ingestion of contaminated food (often pork, vacuum-packed deli meat, beef, lamb, and chicken), unpasteurized milk, and contaminated water. There are several reports of gastroenteritis, especially in infants who were infected by caretakers who had improperly handled raw pork chitterlings (pork intestines) during food preparation procedures. A major concern regarding the potential risk of transmitting this organism is its ability to survive in cold temperatures; food refrigeration is an ineffective preventive measure. In addition, *Y. enterocolitica* sepsis

associated with the transfusion of contaminated packed red blood cells has been reported.

Y. enterocolitica infections manifest in several forms: acute gastroenteritis, appendicitis-like syndrome (mesenteric lymphadenitis), terminal ileitis, and less frequently, septicemia, arthritis, and erythema nodosum. The incidence of systemic infection is higher among children, older adults, or those with underlying diseases, such as liver cirrhosis, diabetes, acquired immunodeficiency syndrome, leukemia, aplastic anemia, and other hematologic conditions. Cases of liver abscess and acute infective endocarditis caused by *Y. enterocolitica* have also been reported. Acute enteritis, the most common form of the infection, is characterized by acute gastroenteritis with fever accompanied by headache, abdominal pain, nausea, and diarrhea. Stools may contain blood. This form of infection, which often affects infants and young children between 1 and 5 years of age, is usually mild and self-limiting in about 7 days.

The clinical form that mimics acute appendicitis occurs primarily in older children and adults. Patients present with severe abdominal pain and fever; the abdominal pain is concentrated in the right lower quadrant. Enlarged mesenteric lymph nodes and an inflamed ileum and appendix are common findings in cases of *Y. enterocolitica* infections. Arthritis is an uncommon extraintestinal form of *Y. enterocolitica* infection, usually after a GI episode or an appendicitis-like syndrome. This form of yersiniosis has been reported more often in adults than in children. Erythema nodosum is an inflammatory reaction caused by *Y. enterocolitica* characterized by tender, red nodules that may be accompanied by itching and burning. The areas involved include the anterior portion of the legs; some patients have reported nodules on their arms. The syndrome is reported to be more common in female patients compared with male patients.

Y. enterocolitica morphologically resembles other *Yersinia* spp., appearing as gram-negative coccobacilli with bipolar staining. The organism also grows on routine isolation media, such as SBA and MAC agar. It has an optimal growth temperature of 25° to 30° C. *Y. enterocolitica* is clearly motile at 25° C but not at 35° C. Appropriate cultures on a specific *Yersinia* medium at 25° C should be performed in diarrheal outbreaks of unknown etiology. Cold enrichment can be used to increase the recovery in fecal samples suspected of containing this organism. Fecal material is inoculated into isotonic saline and kept at 4° C for 1 to 3 weeks, with weekly subculturing to selective agar for *Yersinia*.

Cefsulodin-irgasan-novobiocin (CIN) agar, a selective medium to detect the presence of *Y. enterocolitica*, incorporates cefsulodin, irgasan, novobiocin, bile salts, and crystal violet as inhibitory agents. This medium, which inhibits normal intestinal microbiota more than MAC agar, provides better opportunities to recover *Y. enterocolitica* from feces. Different formulations of CIN are available; for example, *Yersinia*-selective agar (YSA) base (BD Diagnostic Systems, Sparks, MD) has a differential property (mannitol) added to the medium. Fermentation of mannitol results in a decrease in pH around the colony, causing the pH indicator, neutral red, to turn red at the center of the colony and the bile to precipitate. Nonfermentation of mannitol produces a colorless, translucent colony. *Y. enterocolitica* ferments mannitol. A modified formulation of the original CIN medium, known as CIN II, or BD *Aeromonas Yersinia* Agar (Becton-Dickinson,

Franklin Lakes, NJ), can be used to simultaneously isolate most *Aeromonas* spp. from stool samples.

Yersinia pseudotuberculosis

Y. pseudotuberculosis, like *Y. pestis*, primarily is a pathogen of rodents, particularly guinea pigs. In addition to farm and domestic animals, birds are natural reservoirs; turkeys, geese, pigeons, doves, and canaries have yielded positive cultures for this organism. The bacteria are also found in the environment, primarily in colder climates, like northern Europe as well as Asia, including Japan. *Y. pseudotuberculosis* causes a disease characterized by caseous swellings called *pseudotubercles*. The disease is often fatal in animals.

Human infections, which are rare, are associated with close contact with infected animals, or their feces, or ingestion of contaminated drink and foodstuff. When the organisms are ingested, they spread to the mesenteric lymph nodes, producing abdominal pain and mesenteric lymphadenitis that is usually self-limiting. The clinical manifestations can include septicemia, primarily in immunocompromised individuals. Infections are most common in children and young adults. *Y. pseudotuberculosis* appears as a typical-looking plague bacillus. It can be differentiated from *Y. pestis* by its motility at 18°

Other genera of the order Enterobacterales

Budvicia

Based on DNA hybridization, *Budvicia* is a group of related organisms in the family Budviciaceae; however, they are not as closely related to the other members of Enterobacterales. These organisms are usually found in water; however, *Budvicia aquatica* has been isolated in clinical specimens.

Buttiauxella

The genus *Buttiauxella*, in the family Enterobacteriaceae, consists of eight species isolated from water. Only *B. agrestis* and *B. noackiae* have been isolated from human specimens. Biochemically, these organisms resemble *Citrobacter* and *Kluyvera* species, but DNA hybridization distinctly differentiates *Buttiauxella* from both genera.

Cedecea

The genus *Cedecea*, in the family Enterobacteriaceae, is composed of four named species: *C. colo*, *C. davisae*, *C. lapagei*, and *C. neteri*. Most have been recovered from sputum, blood, urine, and wounds. Of the four, *C. davisae* is the most common clinical isolate.

Ewingella

Within the family Yersiniaceae, *Ewingella americana* is the only named species in the genus *Ewingella*. Most isolates have come from human blood cultures or respiratory specimens and exhibit resistance to multiple antimicrobial agents.

Leclercia

The name *Leclercia* was proposed in 1986 for 58 isolates from human clinical specimens including blood, urine, sputum, and feces and 27 isolates from nonhuman sources. It has been isolated more recently in pure culture from septicemia and wounds. The single species is *L. adecarboxylata*, which can have a yellow pigment but only on initial isolation. Although it has similar IMViC reactions to *E. coli*, it is negative for lysine and ornithine decarboxylase and arginine dihydrolase (i.e., triple decarboxylase–negative). It resides in the family Enterobacteriaceae.

Leminorella

Leminorella was proposed as a genus, in the family Budviciaceae, with two species: *L. grimontii* and *L. richardii*. These organisms produce H₂S and have shown weak reactions with *Salmonella* antisera. However, biochemical testing differentiates *Leminorella* from *Salmonella*; *Leminorella* spp. are

relatively inactive. The clinical significance of these organisms is unknown; however, they have been isolated from patients with hospital-acquired infections.

Moellerella

The genus *Moellerella*, within the family Morganellaceae, contains one species, *M. wisconsensis*. The species is positive for citrate, methyl red, lactose, and sucrose. It is negative for lysine, ornithine, arginine decarboxylase, and indole, and it resembles *E. coli* growing on enteric media. The clinical significance of this organism has not been established, although it has been isolated from feces in cases of diarrhea, infected gallbladders, and a bronchial aspirate.

Rahnella

Rahnella, in the family Yersiniaceae, is the name given to a group of seven named species that are psychrotolerant, growing at 4°C. These organisms have no single characteristic that distinguishes them from the other members of the Enterobacterales. They resemble *P. agglomerans*; however, they can be distinguished by their weak phenylalanine deaminase reaction; negative result for potassium cyanide (KCN), gelatin, lysine, ornithine, and motility; and lack of yellow pigmentation. They have been occasionally isolated from human clinical specimens, including wound infections, bacteremias, feces from patients with acute gastroenteritis, and septicemia, especially from immunocompromised patients.

Tatumella

The genus *Tatumella*, in the family Erwiniaceae, contains six species. These organisms are unusual for the Enterobacterales in several ways: stock cultures can be kept frozen in sheep red blood cells or freeze-dried, but they die in a few weeks on agar slants; they show more biochemical reactions at 25° C than at 35° C; they are motile at 25° C but not at 35° C; and they demonstrate large 15- to 36-mm zones of inhibition around penicillin disks. In addition, *Tatumella* isolates are slow growing, produce tiny colonies, and are relatively nonreactive in laboratory media. These organisms have been isolated from human sources, especially sputum, and may be a rare cause of infection. Their reservoir is unknown.

Laboratory diagnosis of the Enterobacterales

Specimen collection and transport

Members of the order Enterobacterales can be isolated from a wide variety of sterile and nonsterile clinical samples. Often these bacterial species are isolated with other organisms, including more fastidious pathogens. To ensure isolation of both opportunistic and fastidious pathogens, laboratories must provide appropriate transport media, such as Cary-Blair, Amies, or Stuart media. Microbiology personnel must encourage immediate transport of clinical samples to the laboratory for processing, regardless of the source of the clinical specimen.

Isolation and identification

To determine the clinical significance of the isolate, the microbiologist must consider the site of origin. Generally, enteric opportunistic organisms isolated from sites that are normally sterile are highly significant. However, careful examination is critical of organisms recovered from, for example, the respiratory tract, urogenital tract, stool, and wounds in open sites that are inhabited by other endogenous microbiota. Members of the order Enterobacterales are routinely isolated from stool cultures; complete identification should be directed only toward true intestinal pathogens. Sputum cultures from hospitalized patients can contain enteric organisms that may require complete identification. Multiplex PCR assays can detect multiple pathogens in clinical specimens. For example, the FilmArray assay can detect 22 common GI pathogens, including bacteria, parasites, and viruses, in about 1 hour. Another FilmArray assay detects 30 microorganisms, including several members of the order Enterobacterales, and 10 drug-resistance genes in a positive blood culture.

Direct microscopic examination

In contrast with gram-positive bacteria, in which microscopic morphology may help provide a presumptive identification, the microscopic characteristics of enterics are indistinguishable from other gram-negative bacilli. However, smears prepared directly from sterile sites, like CSF and other body fluids or exudates, can be examined microscopically for the presence of gram-negative bacteria. Although this examination is non-specific for enteric organisms, this presumptive result can aid the clinician in the preliminary diagnosis of the infection, and appropriate empiric therapy can be instituted immediately.

Direct smears prepared from samples containing endogenous microbiota, such as sputum, do not provide valuable information because their significance cannot be fully assessed unless the gram-negative bacteria are prevalent and endogenous inhabitants are absent. Direct smear examination of stool samples is not helpful in identifying enteric pathogens but may reveal the presence of inflammatory cells. This information may be helpful in determining whether a GI disease is a toxin-mediated or invasive process.

Culture

Members of the Enterobacterales are facultative anaerobes, and most clinically significant species grow at an optimal temperature of 35° to 37° C. Certain species can grow at low temperatures (1° to 5° C, such as *Serratia* and *Yersinia*) or tolerate high temperatures (45° to 50° C, such as *E. coli*). Colonies become visible on nonselective and differential media after 18 to 24 hours of incubation. Most laboratories use a wide variety of nonselective media, such as SBA and CHOC agar, as well as selective media, such as MAC agar, to recover enteric organisms from wounds, respiratory tract secretions, urine, and sterile body fluids. On CHOC agar or SBA plates, enteric bacteria produce large, grayish, smooth colonies. On SBA, colonies may be β -hemolytic or nonhemolytic.

Screening stool cultures for pathogens

Because of the mixed microbial biota of fecal specimens, efficient screening methods must be used for the recovery

and identification of enteric pathogens. All fecal specimens should be routinely screened for *Salmonella*, *Shigella*, STEC, and *Campylobacter* (see Chapter 20). Laboratory protocols and media should also be available for *Yersinia*, *Aeromonas*, *Vibrio*, and *P. shigelloides* when appropriate or requested. Screening routinely for the additional organisms may not be cost-effective, but they should be addressed based on patient history (e.g., travel near coastal areas or developing countries where certain organisms are endemic) and gross description of the specimen (bloody or watery).

Stool specimens contain enteric organisms as normal intestinal microbiota; in processing stool samples, laboratories develop their own protocol for the maximum recovery of enteric pathogens. Fecal pathogens are generally nonlactose fermenters (NLFs). These organisms appear as clear or colorless and translucent colonies on MAC agar. However, many of the bacteria that compose common fecal microbiota also appear as NLFs (e.g., *Proteus* and *Providencia*) as well as delayed lactose-fermenting organisms (e.g., *Serratia* and *Citrobacter*). For this reason, it is necessary to use screening tests to differentiate these organisms from pathogens found in feces. One approach is to take a well-isolated, NLF colony and perform a screening battery of tests consisting first of an oxidase test and the inoculation of lysine iron agar (LIA) and TSI agar slants (Table 19.11). If the screening tests rule out pathogenic organisms, the process is complete, and the culture is discarded (after 48 hours of incubation).

Most clinical microbiologists inoculate stool samples on highly selective media, such as HE or XLD agars, in addition to MAC and SMAC agars for *E. coli* O157:H7. An enrichment broth (e.g., selenite, GN) has been traditionally inoculated to enhance recovery. As previously mentioned, CIN II agar can serve the dual purpose of screening for *Y. enterocolitica*, and most *Aeromonas* spp. *Y. enterocolitica* produces pale rose colonies with a dark red center ("bull's eye"), whereas *Aeromonas* spp. form colorless to rose-colored colonies with a rose center. One must remember that *Yersinia* is oxidase-negative, *Aeromonas* is oxidase-positive, and testing for this trait must be done on SBA, not on selective or differential media. The oxidase-positive *P. shigelloides*, a potential enteric pathogen, produces opaque colonies without a pink center (mannitol nonfermenter) on CIN agar.

On HE agar, lactose-fermenting species produce yellow colonies, whereas NLFs such as *Shigella* spp. produce green colonies (Fig. 19.11). *Salmonella* spp. are NLFs, creating green colonies with black centers from H₂S production. However, *Proteus* spp. are NLFs, and species that produce H₂S also appear green with black centers on HE agar. *Salmonella* Paratyphi is the only serotype that is H₂S negative. *C. freundii* usually produces yellow colonies with black centers. NLF species such as *Salmonella enterica*, which produces lysine decarboxylase, produce red colonies with black centers on XLD medium (Fig. 19.12).

Another selective and differential medium is *Salmonella-Shigella* (SS) agar, a light straw-colored medium in which *Salmonella* colonies appear colorless with dark black centers from H₂S production, and *Shigella* colonies appear as colorless colonies only. *E. tarda*, a potential enteric pathogen, produces colonies that resemble *Salmonella*: NLF and H₂S producer. On CHROMagar *Salmonella*, *Salmonella* isolates produce mauve-colored colonies (Fig. 19.13) resulting from the activity of an esterase on a patented substrate. Other members of

the order Enterobacterales produce blue or white colonies. Each laboratory must decide which media work best in their situation and patient population. Many larger clinical laboratories employ multiplex PCR (e.g., FilmArray) directly on fecal samples, thus eliminating the need for stool cultures.

Identification

The identification of members of the order Enterobacterales can be accomplished in several ways. The clinical

microbiologist can presumptively determine utilization of carbohydrates by observing the colony morphology of the isolate on differential or selective media such as MAC, SMAC, CIN, HE, or XLD. To identify an isolate, the clinical microbiologist first must determine whether the isolate belongs to the order Enterobacterales. All members of the order (1) are oxidase negative except *P. shigelloides*, (2) ferment glucose, and (3) reduce nitrate to nitrite except *Photorhabdus* (rare human isolate) and *Xenorhabdus*

Fig. 19.13 *Salmonella* growing on CHROMagar *Salmonella* differential agar. (Courtesy BD Diagnostic Systems, Sparks, MD.)

(environmental isolate). Gram-negative isolates, especially NLFs, should be tested for cytochrome oxidase production. The oxidase test should always be performed using young growth from an SBA plate. Testing colonies from highly selective media such as CIN can give a false-negative reaction, whereas MAC and EMB agars may give the appearance of a false-positive reaction from the pH indicators and dyes present in the media.

A few laboratories choose to use conventional biochemical tests in tubes, whereas others may prefer miniaturized or automated commercial identification systems. See [Chapter 9](#) for a thorough description of the currently available rapid and automated commercial identification systems. The use of conventional biochemical tests in tubes is cumbersome because of the large number of biochemical tests available.

Sometimes, a few biochemical tests, such as LIA and TSI mentioned earlier, can be performed to rule out potential enteric pathogens. The Clinical and Laboratory Standards Institute has created several abbreviated test protocols for the identification of common bacterial isolates. For example, a gram-negative bacillus that forms nonswarming, β -hemolytic colonies and is spot indole positive is identified as *E. coli*. Occasional isolates that are not β -hemolytic must be indole-positive and lactose-positive on MAC or EMB, and they must exhibit a negative pyrrolidonyl arylamidase (PYR) test to be identified as *E. coli*.

Many clinical laboratories develop identification tables and protocols using a limited number of tests that suit their workflow and capabilities. Identification tables are based on the key features necessary to identify each genus and clinically relevant species. [Fig. 19.14](#) shows an example of a schematic diagram for the identification of commonly isolated enterics using conventional biochemical tests. [Table 19.12](#) shows the differentiating characteristics of the species, subspecies, biogroups, and serotypes of the Enterobacterales. As their costs

have decreased, the use of molecular biology assays is becoming more frequent. These assays include DNA probes, NAATs, the Microbial Identification System (MIDI, Newark, DE), and MALDI-TOF mass spectrometry.

Serologic grouping

When an isolate is biochemically identified as *Salmonella* or *Shigella*, serologic grouping of the isolate for the O serogroups (oligosaccharide somatic antigen) must be performed for confirmation. Serologic grouping is also important in the identification of enterovirulent *E. coli* strains.

Salmonella

Salmonella isolates can be typed using O, H, and Vi antigens. Based on O antigens, *Salmonella* can be placed into major serogroups designated by capital letters. Approximately 47 somatic O antigenic groups exist; however, 95% of *Salmonella* isolates from humans belong to serogroups A through E1. Originally, serogroups were designated by letters of the alphabet. However, because there are more serogroups than letters, numbers were also used. Currently, it is recommended to simply use the O antigen number designation for the serogroup and not use letters. For example, all members of serogroup A express O antigen 2. The current designation for the serogroup is O:2 ([Table 19.13](#)).

It is imperative for laboratories to be able to identify *Salmonella* serotype Typhi, in particular, serologically and other members of *Salmonella* in serogroups A to G (O:13). Other isolates can be reported as “biochemically compatible with *Salmonella*” and submitted to a reference laboratory for further identification. If an isolate is suspected of being *Salmonella* Typhi, *Salmonella* Paratyphi, or *Salmonella* Choleraesuis, it must be biochemically identified and serologically confirmed because of the medical implications. Identification is very important in providing proper therapy for the patient and in limiting possible complications.

To perform serologic grouping by the slide technique, a suspension from a pure culture of the organism is prepared in sterile saline solution. Serologic typing is best performed on a colony taken from a pure culture growing on nonselective media, such as an SBA plate, although TSI or MAC agar can be used for presumptive serologic identification.

A slide with wells is easy to use for the agglutination test. A regular microscope slide may be used by marking separate circles with a wax pencil. The laboratory scientist places one drop of antisera on the appropriately labeled slide. One drop of bacterial suspension is added to each drop of antisera for a direct agglutination assay. Antisera kits usually consist of a polyvalent A to G, Vi, and individual antisera for serogroups A, B, C1–C4, C2–C3, D, E, and G. Latex agglutination kits offer improved visibility of agglutination reactions; this is an example of reverse passive agglutination.

The Vi antigen is found on *Salmonella* Typhi and occasionally other serotypes and can mask the O antigens. In the event of a positive agglutination in the Vi antisera with no agglutination in the other groups, the suspension should be heated to 100° C for 10 minutes to inactivate the capsular Vi antigen. The suspension is then cooled and retested with antisera A to G. Larger laboratories usually maintain antisera to serogroup

Fig. 19.14 Flowchart for the presumptive identification of commonly encountered Enterobacterales on triple sugar iron (TSI) agar. A, Acid; IMV:C, indole, methyl red, Voges-Proskauer, citrate; K, alkaline; NLF, nonlactose fermenter; PAD, phenylalanine deaminase. (Data from Koneman, E., et al. [1997]. *Color atlas in diagnostic microbiology* [5th ed.]. Philadelphia: Lippincott-Raven.)

salmonellae for all somatic types. H antigen (flagellar) typing and next-generation sequencing technology are usually performed in a state or reference laboratory providing epidemiologic information in outbreaks.

Shigella

Similar serogrouping procedures may be used in the serologic testing for *Shigella*. Serologic grouping of *Shigella* is also based on the somatic O antigen. However, *Shigella* spp. are nonmotile and do not express H antigen. Antigenic typing is necessary to differentiate the *Shigella* spp. from inactive *E. coli* and to confirm the identification of individual species. *Shigella* spp. belong to one of four serogroups: A (*S. dysenteriae*), B (*S. flexneri*), C (*S. boydii*), and D (*S. sonnei*). The O antisera used for serogrouping are polyvalent, containing several serotypes within each group (except for group D, which contains only a single serotype). If agglutination fails, the suspension must be heated to remove the capsular antigen that might be

present, and subsequently the agglutination test procedure is repeated.

Plesiomonas shigelloides

P. shigelloides can be presumptively differentiated from similar genera with several key tests. The positive oxidase activity separates it from other Enterobacterales, sensitivity to the agent O/129 separates it from *Aeromonas*, and its ability to ferment inositol separates it from all *Aeromonas* and almost all *Vibrio* spp. It can also be separated from the halophilic *Vibrio* spp. by its ability to grow in nutrient broth with 0% NaCl and its inability to grow in nutrient broth with 6% NaCl.

Most biochemical identification systems include *P. shigelloides* in their databases and appear to be able to identify it with a high degree of accuracy. This is in large part because of its unique, positive trio profile of ornithine and lysine decarboxylases and arginine dihydrolase reactions, combined with the fermentation of inositol. It is also included in the PCR-based FilmArray GI panel.

^aEach number is the percentage of positive reactions after 2 days of incubation at 36° C unless noted otherwise. Most of these positive reactions occur within 24 hours. Reactions that become positive after 2 days are not considered.

H₂S, Hydrogen sulfide; KCN, potassium cyanide; ONPG, o-Nitrophenyl-β-D-galactopyranoside; TSI, triple sugar iron.

Table 19.13 Designation of *Salmonella* serogroups of most clinical significance

Old designation	New designation
A	2
B	4
C ₁ -C ₄	6, 7
C ₂ -C ₃	8
D ₁	9
D ₂	9, 46
D ₃	9, 46, 27
E ₁ -E ₂ -E ₃	3, 10
E ₄	1, 3, 19
F	11
G ₁ -G ₂	13

From Grimont, P. A. D., & Weill, F.-X. (2007). *Antigenic formulae of the Salmonella serovars*, 2007. (9th ed.). Paris, France: WHO Collaborating Centre for Reference and Research on *Salmonella*.

POINTS TO REMEMBER

- Most of the genera discussed in this chapter could conceivably be isolated from almost any clinical specimen, especially when dealing with immunocompromised patients.
- Although most isolates of *E. coli* are considered normal fecal microbiota, several strains (enterovirulent *E. coli*) are known to cause intestinal tract infections; in the United States STEC is the most notable. *E. coli* is the most significant cause of UTIs.
- ETEC strains can produce LT and/or ST.
- EIEC strains genetically and phenotypically resemble *Shigella* spp.
- STEC strains produce Shiga toxin 1 and/or Shiga toxin 2. Some of these strains, referred to as EHEC, produce a more severe infection called HUS.
- *Salmonella* and *Shigella* are enteric pathogens and are not considered normal fecal biota.
- *Yersinia pestis*, one of the most virulent species in the order Enterobacterales, causes the extraintestinal infection plague.
- A good patient history combined with proper selective screening agar (e.g., HE, XLD, and SMAC agars) can be very helpful in the timely and accurate identification of enteric pathogens associated with diarrheal disease.
- The use of an initial battery of selective agar media and key biochemical tests that include an oxidase test, TSI, urea, and LIA can often result in a presumptive genus identification that can be confirmed with either conventional biochemical tests, one of several multitest or rapid and automated identification systems, or a molecular biology assay.
- Serogrouping is an important aspect in the identification of enteric pathogens.

LEARNING ASSESSMENT QUESTIONS

- S. dysenteriae*
 - S. flexneri*
- Which of the following test results is most helpful in categorizing an isolate as a member of the family Moraxellaceae?
 - Positive urea
 - Positive Voges-Proskauer
 - Positive phenylalanine deaminase
 - Positive lactose fermentation
- Which agent is most often the cause of transmission of bubonic plague to humans?
 - Fleas
 - Mosquitos
 - Dog bites
 - Inhalation
- A 47-year-old patient who just returned from Mexico was admitted to the hospital with a 3-day history of vomiting and diarrhea, without fever. No fecal leukocytes were found in the stool. A stool culture grew an organism identified as *Escherichia coli*. Which strain is the most likely cause of the infection?
 - EPEC
 - ETEC
 - ESTEC
 - EIEC
- A gram-negative, oxidase-negative bacillus was isolated from the cerebrospinal fluid of an infant in the newborn nursery. The organism produced dark pink colonies on MAC agar, was β -hemolytic on SBA, and had the following biochemical results: spot indole positive, triple sugar iron, acid over acid with gas; urease-negative; and citrate-negative. What is the most probable identity of this organism?
 - Escherichia coli*
 - Klebsiella aerogenes*
 - Klebsiella pneumoniae*
 - Serratia marcescens*
- Which member of the order Enterobacterales is often associated with lobar pneumonia in hospitalized older adults?
 - Shigella* spp.
 - Proteus vulgaris*
 - Escherichia coli*
 - Klebsiella pneumoniae*
- What is the most common cause of community-acquired urinary tract infections?
 - Klebsiella pneumoniae*
 - Escherichia coli*
 - Providencia stuartii*
 - Citrobacter freundii*
- Which organism is an opportunistic pathogen that can cause wound and urinary tract infections and the production of kidney stones?
 - Yersinia enterocolitica*
 - Citrobacter freundii*
 - Proteus mirabilis*
 - Enterobacter cloacae*
- Which of the following is an enteric organism that is acquired by eating improperly prepared and cooked or preserved food that is contaminated with human feces and produces dysentery?
 - Proteus vulgaris*
 - Yersinia enterocolitica*
 - Serratia marcescens*
 - Shigella* spp.

11. An organism isolated from a stool culture produces colorless colonies on MAC agar, green colonies with black centers on Hektoen enteric agar, and K/A H₂S positivity in TSI agar. It is urease negative, motile, and phenylalanine deaminase negative. What is the most likely identification of the organism?
 - a. *Proteus vulgaris*
 - b. *Yersinia enterocolitica*
 - c. *Salmonella* spp.
 - d. *Shigella* spp.
12. Which of the following organisms causes infections that present with watery stools followed by bloody stools, abdominal cramping, low-grade fever, and hemorrhagic diarrhea, especially in children?
 - a. *E. coli* O157:H7
 - b. *Shigella sonnei*
 - c. *Salmonella enterica*
 - d. *Yersinia enterocolitica*
13. A 4-year-old boy is admitted to the hospital because of lower-right quadrant pain and a fever of 102° F. The white blood cell count was 15,000/mm³ with 75% PMN and 6% bands. The presumptive diagnosis is acute appendicitis. At surgery, the appendix is grossly normal, but several enlarged red mesenteric lymph nodes are observed. One of the lymph nodes is excised and sent to the laboratory for culture. Which of the following organisms is most likely to produce this clinical picture?
 - a. *Yersinia enterocolitica*
 - b. *Citrobacter freundii*
 - c. *Proteus mirabilis*
 - d. *Enterobacter cloacae*
14. Which of the following organisms would you most likely recover from an infected gallbladder?
 - a. *Escherichia coli* O157:H7
 - b. *Shigella sonnei*
 - c. *Salmonella* spp.
 - d. *Yersinia enterocolitica*
15. A suspected stool pathogen appears as non motile, gram-negative rods. It is H₂S negative, is oxidase negative, does not produce gas when glucose is fermented, and agglutinates the *Shigella* antisera group D. What is the most likely identification of the organism?
 - a. *S. sonnei*
 - b. *S. boydii*
 - c. *S. dysenteriae*
 - d. *S. flexneri*

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Discuss the habitat in which the organisms discussed in this chapter are found.
2. Describe the colony morphology and microscopic characteristics of each organism.
3. Apply the appropriate specimen, transport, and processing for maximum recovery of each organism.
4. Justify the media of choice for isolation of each organism.
5. Discuss key biochemical reactions that will help differentiate among the various genera and identify different species.
6. Compare each group of organisms with respect to macroscopic and microscopic morphology, and biochemical reactions for identification.

7. Compare the epidemiology and clinical infections of each group of organisms.
8. Compare the confirmatory tests commonly used to identify these isolates.
9. Discuss the criteria used to differentiate the bacterial species that cause gastrointestinal illnesses.
10. Explain the risk factors associated with acquiring infections by these organisms.
11. Describe the disease states associated with each group of organisms.

KEY TERMS

Asiatic cholera
 Cholera toxin
 Choleragen
 “Darting” motility
 El Tor
 Halophilic

Kanagawa phenomenon
 Microaerophilic
 Thiosulfate citrate bile salt sucrose (TCBS) agar
 Type B gastritis
 Urea breath test

Case in point

A 65-year-old Chinese male patient, in obvious shock, was examined in the emergency department for a painful swelling of the left hand. His medical history revealed bilateral knee joint pain and posthepatic cirrhosis. The day before admission, he had pricked his left index finger while selecting shrimp at a fish market. Initially, he noticed only a local reaction in his finger, but after 12 hours the left hand began to swell. He later experienced nausea, vomiting, and diarrhea. The patient was now clammy with a weak pulse, marked swelling, and bullous formation with gangrenous changes apparent on the left hand. A diagnosis of septic shock was made, and antimicrobial therapy was initiated. Blood and wound cultures subsequently grew an oxidase-positive, gram-negative bacillus that produced pink colonies on MacConkey (MAC) agar and green colonies on **thiosulfate citrate bile salt sucrose (TCBS)** agar and required 3% to 6% NaCl for growth. No acceptable identification could be made with a rapid identification system for gram-negative

bacilli, and final identification was made with conventional biochemicals supplemented with 1% NaCl. The patient suffered a cardiac arrest and died 11 hours after admission.

Issues to consider

After reading the patient's case history, consider:

- Various pathogenic organisms associated with aquatic life that cause human infections
- Disease spectrum and states associated with these organisms
- Presentation of clinical signs and symptoms
- Media of choice to aid in a rapid diagnosis
- Key biochemical reactions to presumptively and definitively identify the organism responsible for this infection
- Treatment of choice for this infectious agent

This chapter discusses agents of diarrheal diseases and other infections caused by species of *Vibrio*, *Aeromonas*, *Campylobacter*, and *Helicobacter*. The microscopic characteristics, epidemiology, and clinical infections caused by each organism are discussed. Specimen collection, transport, growth requirements, and key biochemical reactions used for diagnosis are also included in this chapter. This group of organisms is important because some of them, the *Vibrio* spp. in particular, have been associated with large epidemics and pandemics. In addition, *Campylobacter* spp. infection may play a role in Guillain-Barré syndrome (GBS), and *Helicobacter pylori* can cause ulcers and has been linked to gastric carcinoma.

Vibrio

The genus *Vibrio* resides in the family Vibrionaceae, which includes 15 genera. To date, only about 15 species within the family have been found in human clinical specimens: *Vibrio* (13 species), *Photobacterium* (1 species), and *Grimontia* (1 species). *Vibrio hollisae* is now classified in the genus *Grimontia* as *G. hollisae*, whereas *Vibrio damsela* has been reclassified as *Photobacterium damsela*.

At least 150 species of *Vibrio* are recognized. *Vibrio* spp. are commonly found in a wide variety of aquatic environments, including fresh water, brackish or estuarine water, and marine or salt water. They are temperature sensitive in that in temperate climates in which water temperatures exceed 20° C, as in the summer months, vibrios can easily be isolated from water, suspended particulate matter, algae, plankton, fish, and shellfish. However, their numbers decline markedly in the winter months, and they are generally found only in the sediments. Therefore the risk of infection from all *Vibrio* spp. can be reduced by the avoidance of eating raw or undercooked shellfish, particularly in warmer summer months. This is especially pertinent for those who are immunocompromised or have serious underlying liver disease. Additionally, those who are severely immunosuppressed should avoid exposure of wounds to fresh, estuarine, and marine water sources.

Several gastrointestinal and extraintestinal infections, caused by *Vibrio* spp. have been reported. Some reasons for the clinical isolation of this organism include:

- Increased ocean water temperature because of climate change
- Increased travel to coastal or cholera-endemic areas

- Increased consumption of seafood (particularly raw or undercooked)
- Increased use of recreational water facilities, which encourages aquatic exposure
- Larger populations of immunocompromised individuals
- Increased awareness of the existence and significance of these organisms in the clinical microbiology laboratory

Pandemics (worldwide epidemics) of cholera, a devastating diarrheal disease caused by *Vibrio cholerae*, have been documented since 1817.

Researchers estimate that approximately 1.3 to 4.0 million cases of cholera occur each year, with deaths tolls ranging from 21,000 to 143,000 worldwide. Although in 2018, the World Health Organization (WHO) reported a 60% decrease in cholera cases worldwide, the number of cases reported to the WHO remains high over the past few years. In 2020, 323,369 cholera cases resulting in 857 deaths were reported from 24 countries. The discrepancy in these numbers was attributed to limited surveillance systems where cases are not being recorded. Nevertheless, in 2017, the Global Task Force on Cholera Control partners launched a strategy for cholera control that aims to reduce cholera deaths by 90% and to eliminate cholera in as many as 20 countries by 2030. In addition, oral vaccine campaigns have been implemented in endemic areas and in areas experiencing an outbreak. The WHO has prequalified three oral cholera vaccines for use; however, they are not available in the United States.

General characteristics

Clinical manifestations

Vibrio spp. can be isolated from a number of clinical sources, and most species have been implicated in more than one disease process, ranging from mild gastroenteritis to cholera and from simple wound infections to necrotizing fasciitis and fatal septicemia. Table 20.1 lists the various clinical infections associated with *Vibrio* spp. The four *Vibrio* spp. most often encountered in the clinical laboratory are *V. cholerae*, *V. parahaemolyticus*, *V. vulnificus*, and *V. alginolyticus*.

Because most laboratories, except those in coastal areas, have a fairly low frequency of isolation of *Vibrio* spp., a good medical history is extremely important. Often the best indication of a possible *Vibrio* infection is the presence of recognized risk factors, such as:

- Recent consumption of raw seafood (especially oysters)
- Recent immigration or foreign travel
- Accidental trauma incurred during contact with fresh, estuarine, or marine water or associated products (e.g., shellfish, oyster or clam shells, fishhooks)

Microscopic morphology

Vibrio spp. are asporogenous, gram-negative rods that measure approximately 0.5 to 0.8 µm in diameter by 1.4 to 2.6 µm in length. Most organisms possess polar, sheathed, monotrichous or multitrichous flagella when grown in broth; however, *V. parahaemolyticus* and *V. alginolyticus* have the ability to swarm on solid media because of the production of lateral

flagella. They have been described typically as curved or comma-shaped gram-negative rods, but this morphology is often seen only in the initial Gram stain of the clinical specimen (Fig. 20.1). Vibrios usually appear as small, straight, gram-negative rods, but they can be highly pleomorphic, especially under suboptimal growth conditions.

Table 20.1 Clinical infections associated with *Vibrio*, *Grimontia*, and *Photobacterium* species

Species	Clinical infection	Frequency
<i>V. cholerae</i> O1	Cholera, gastroenteritis, wound infections, bacteremia	Common
<i>V. cholerae</i> O139	Cholera	Common
<i>V. cholerae</i> non-O1	Gastroenteritis, septicemia, brain abscesses, ear infections	Relatively common
<i>Vibrio parahaemolyticus</i>	Gastroenteritis, wound infections	Common
<i>Vibrio vulnificus</i>	Septicemia, wound infections	Common
<i>Vibrio alginolyticus</i>	Wound infections, ear infections, conjunctivitis, respiratory infections, bacteremia	Common
<i>Vibrio mimicus</i>	Gastroenteritis, ear infections	Uncommon
<i>Vibrio fluvialis</i>	Gastroenteritis	Uncommon
<i>Vibrio furnissii</i>	Gastroenteritis	Uncommon
<i>Vibrio cincinnatiensis</i>	Meningitis, bacteremia	Rare
<i>Vibrio metschnikovii</i>	Septicemia, peritonitis	Rare
<i>Vibrio harveyi</i>	Wound infections	Rare
<i>Grimontia holisae</i>	Gastroenteritis	Uncommon
<i>Photobacterium damsela</i>	Wound infections (cellulitis; necrotizing fasciitis), bacteremia	Uncommon

From Tarr C. L., et al. (2015). *Vibrio* and related organisms. In J. H. Jorgensen, et al. (Eds.), *Manual of clinical microbiology* (11th ed., p. 762). Washington, DC: ASM Press.

Physiology

The vibrios are facultatively anaerobic, and all 13 clinically significant species are catalase and oxidase positive and able to reduce nitrate to nitrite, except for *V. metschnikovii*, which is negative for all three tests. Most species are generally susceptible to the vibriostatic compound O/129 (2,4-diamino-6,7-diisopropylpteridine), exhibiting a zone of inhibition to a 150-μg vibriostatic disk on Mueller-Hinton or trypticase soy agar (Fig. 20.2). However, this test is not as valuable with isolates from India and Bangladesh, in which resistance to both 10- and 150-μg disks to O/129 is common in *V. cholerae* isolates.

Most vibrios, including *V. cholerae*, also exhibit a positive string test observed as a mucoid “stringing” reaction after emulsification of colonies in 0.5% sodium deoxycholate. This occurs as a result of the release of deoxyribonucleic acid (DNA) from lysed cells. All species, except for *V. cholerae* and *V. mimicus*, are **halophilic**, or salt-loving, and require the addition of Na⁺ for growth. Vibrios can be differentiated from the similar genera *Aeromonas* and *Plesiomonas* (now classified in the order Enterobacterales, see Chapter 19) by key biochemical and growth requirement characteristics, as shown in Table 20.2.

Antigenic structure

Little is known about the antigenic structure of *Vibrio* except for *V. cholerae*, *V. parahaemolyticus*, and, to a lesser degree, *V. fluvialis* and *V. vulnificus*. Over 200 serogroups of *V. cholerae*

Sucrose	+ / –	+ / –	–
Gelatin liquefaction	+	+	–

^aVibriostatic agent (2,4-diamino-6,7-diisopropylpteridine).
 +, most strains positive; –, most strains negative; +/– or – / +, predominant reaction first; NA, not available; R, resistant; S, susceptible; V, variable.
 From Tarr, C. L., et al. (2019). *Vibrio* and related organisms. In K. C. Carroll, et al. (Eds.), *Manual of clinical microbiology* (12th ed., pp. 775–786). Washington, DC: ASM Press.

have been reported. The three major groups of *V. cholerae* are *V. cholerae* O1, *V. cholerae* O139, and *V. cholerae* non-O1, non-O139, all of which share a common flagellar (H) antigen and somatic (O) antigen. Only serogroups O1 and O139 have been responsible for pandemics and large epidemics. Based on the composition of the O antigen, *V. cholerae* O1 organisms are divided into the following serotypes: Ogawa (A, B), Inaba (A, C), and Hikojima (A, B, C; very rarely isolated). Strains that phenotypically resemble *V. cholerae* but fail to agglutinate in O1 antisera are referred to as *V. cholerae* non-O1. *V. parahaemolyticus* can also be serotyped by means of its O and K (capsule) antigens, but this is generally done only during epidemiologic studies conducted by reference laboratories.

Vibrio cholerae

Epidemiology

Vibrio cholerae O1 is the causative agent of cholera, also known as Asiatic cholera or epidemic cholera. It has been a disease of major public health significance for centuries. Most epidemics occur in developing countries, in which it is endemic. In particular, cholera is prevalent in the Bengal region of India and Bangladesh. The seventh and current pandemic of cholera originated in Indonesia in 1961. The pandemic strain, *V. cholerae* O1, spread quickly throughout Asia and reached the African continent in 1970. Cholera returned to South America in 1991 for the first time in almost a century and advanced northward into Central America and even Mexico. In addition, a derivative of the biotype El Tor was responsible for causing a major epidemic in Bangladesh in 1992. In October 2010, a cholera outbreak occurred in Haiti, 10 months after a devastating earthquake. It affected over 820,000 people and killed almost 10,000, and it is considered the worst outbreak

in recent history. The WHO and the Pan American Health Organization (PAHO) reported in January 2020 that the country has achieved 1 year free from confirmed cases of cholera, with the last case reported in January 2019. Cases of cholera are not commonly reported in the United States, and most cases are considered imported cases.

Clinical manifestations

Cholera is an acute diarrheal disease that spreads mainly through contaminated water. However, improperly preserved and handled foods, including fish and seafood, milk, ice cream, and unpreserved meat, have been responsible for outbreaks. The disease manifests in acute cases as a severe gastroenteritis accompanied by vomiting and followed by diarrhea. The stools produced by patients with cholera are described as *rice water stools*, and the number of stools, which are watery and contain numerous flecks of mucus, may be as many as 10 to 30 per day. If left untreated, cholera can result in a rapid fluid and electrolyte loss that leads to dehydration, hypovolemic shock, metabolic acidosis, and death in a matter of hours.

The devastating clinical scenario is the result of a powerful enterotoxin known as **cholera toxin**, or **cholera toxin**. Once ingested, the bacteria colonize the small intestine, in which they multiply and produce cholera toxin. The toxin consists of two toxic A subunits and five binding B subunits. The toxin initially binds to the GM₁ ganglioside receptor on the cell membrane via the B subunits. The A2 subunit then facilitates the entrance of the A1 subunit. Once inside the cell, the active A1 subunit stimulates the production of adenylate cyclase through the inactivation of G protein. This leads to an accumulation of cyclic adenosine monophosphate (cAMP) along the cell membrane, which stimulates hypersecretion of electrolytes (Na⁺, K⁺, HCO₃[–]) and water out of the cell and into the lumen of the intestine, as shown in Fig. 20.3. The net effect is that the gastrointestinal tract's absorptive ability is overwhelmed, resulting in the massive outpouring of watery stools.

Treatment and management of cholera are best accomplished by the administration of copious amounts of intravenous or oral fluids to replace fluids lost from the severe diarrhea. The administration of antimicrobial agents such as doxycycline can shorten the duration of diarrhea and thereby reduce fluid loss; however, resistance to doxycycline has been reported. Therefore administration of additional antimicrobials such as azithromycin and ciprofloxacin may be necessary.

Epidemic *V. cholerae* O1 strains occur in two biogroups, classic and **El Tor**. El Tor has been the predominant biogroup in the past two pandemics. Studies in Bangladesh, however, indicate a rapidly occurring reemergence of the classic biogroup. In addition, new variants have emerged in Africa and Asia. The El Tor biogroup differs from the classic biogroup in that El Tor is Voges-Proskauer positive, hemolyzes erythrocytes, is inhibited by polymyxin B (50 µg), and is able to agglutinate chicken red blood cells. The two biogroups also have different bacteriophage susceptibility patterns.

Numerous cases of *Vibrio* infections have been reported involving other serogroups, *V. cholerae* non-O1. Most of these strains are phenotypically similar to toxigenic *V. cholerae* O1, but most lack the cholera toxin gene and appear to cause a milder form of gastroenteritis or cholera-like disease. However, *V. cholerae* serogroups O75 and O141 harbor the cholera toxin gene and have been associated with sporadic,

Fig. 20.3 The action of cholera toxin. The complete toxin is shown binding to the GM1 ganglioside receptor on the cell membrane via the binding (B) subunits. The active portion (A1) of the A subunit catalyzes the adenosine diphosphate ribosylation (ADPR) of the G_s (stimulatory) regulatory protein, “locking” it in the active state. Because the G protein acts to return adenylate cyclase from its active to inactive form, the net effect is persistent activation of adenylate cyclase. The increased adenylate cyclase activity results in accumulation of cyclic adenosine 3', 5'-monophosphate (cAMP) along the cell membrane. The cAMP causes the active secretion of sodium (Na⁺), chloride (Cl⁻), potassium (K⁺), bicarbonate (HCO₃⁻), and water out of the cell into the intestinal lumen. ATP, Adenosine triphosphate. (From Ryan, K. J. [2004]. *Vibrio and Campylobacter*. In J. Sherris (Ed.), *Medical microbiology: an introduction to infectious diseases* [4th ed., p. 375]. New York: McGraw-Hill.)

cholera-like diarrhea and bloodstream infections in the United States. Other non-O1 serogroup strains have been implicated in a variety of extraintestinal infections, including epidural brain abscesses and septicemia. The emergence of *V. cholerae* serogroup O139 in 1992 led to a widespread occurrence of cholera cases throughout India and Bangladesh. This was the first *V. cholerae* non-O1 strain producing epidemic disease. The O139 strain contains the cholera toxin gene, *ctx*, and produces a disease that closely resembles cholera caused by *V. cholera* O1. Of interest is that some of these O139 strains share cross-reacting antigens with *Aeromonas trota*, a somewhat uncommon cause of diarrheal disease (discussed later).

Vibrio parahaemolyticus

Epidemiology

Vibrio parahaemolyticus is the second most common *Vibrio* species implicated in gastroenteritis after *V. cholerae*. In the United States, however, it is the most frequently encountered

species in clinical samples. This species was first recognized as a pathogen in Japan in 1950, when it caused a large food poisoning outbreak. Even today it is the primary cause of so-called *summer diarrhea* in Japan. *V. parahaemolyticus* has also been isolated in Europe, the Baltic area, Australia, Africa, Canada, and almost every coastal state in the United States. Most cases of *V. parahaemolyticus* reported before 1996 were associated with various serotypes; however, after 1996, a pandemic strain of *V. parahaemolyticus* serotype O3:K6 emerged and has since been implicated in numerous foodborne outbreaks in various parts of the world.

Like other vibrios, *V. parahaemolyticus* is found in aquatic environments but appears to be limited to coastal or estuarine areas, despite a halophilic requirement of 1% to 8% NaCl. *V. parahaemolyticus* has an association with at least 30 different marine animal species, including oysters, clams, crabs, lobsters, scallops, sardines, and shrimp. Hence, most cases of gastroenteritis can be traced to recent consumption of raw, improperly cooked, or recontaminated seafood, particularly oysters.

In 2019, the Centers for Disease Control and Prevention (CDC) reported a multistate outbreak of gastrointestinal illness linked to oysters imported from Mexico. A total of 16 individuals from 5 states became ill after ingesting the contaminated food. Two people were hospitalized; however, no deaths were reported.

Clinical manifestations

The gastrointestinal disease caused by *V. parahaemolyticus* is generally self-limiting. Patients have watery diarrhea, moderate cramps or vomiting, and low, if any, fever. Symptoms begin about 24 to 48 hours after ingestion of contaminated seafood. *V. parahaemolyticus* has occasionally been isolated from extraintestinal sources such as wounds, ear and eye infections, and even cases of pneumonia. Invariably the patient has a history of recent aquatic exposure or a water-associated traumatic injury to the infected site.

The pathogenesis of *V. parahaemolyticus* is not as well understood as *V. cholerae*. However, there is a possible association between hemolysin production and virulence, known as the **Kanagawa phenomenon**. It has been observed that most clinical *V. parahaemolyticus* strains produce a heat-stable hemolysin that is able to lyse human erythrocytes in a special, high-salt mannitol medium (Wagatsuma agar). These strains are considered Kanagawa toxin positive, whereas most environmental isolates are Kanagawa toxin negative. There are exceptions to both observations, however, and the exact role of this hemolysin in pathogenesis is still not understood. It is also important to note the recent emergence of atypical urease-positive *V. parahaemolyticus* strains from clinical sources along the Pacific coast of North America.

Vibrio vulnificus

Vibrio vulnificus can be found in marine environments on the Atlantic, Gulf, and Pacific coasts of North America. After cholera, the second most serious types of *Vibrio*-associated infections are those caused by *V. vulnificus*. Infections caused by *V. vulnificus* generally fall into two categories, primary septicemia and wound infections. The former is thought to occur through the gastrointestinal route after the consumption of shellfish, especially raw oysters. Patients with liver dysfunction and syndromes that result in increased serum levels of iron (e.g., hemochromatosis, cirrhosis, thalassemia major, hepatitis) are particularly predisposed to this scenario. Within hours, septicemia can develop, with a mortality rate above 50%. Starting in 2007, the CDC required that cases of *V. vulnificus* be reported to local and state public health departments.

Patients with *V. vulnificus* wound infections invariably have a history of some type of traumatic aquatic wound that often presents as a cellulitis. Such cases have also been documented as progressing to necrotizing fasciitis and/or

multiple organ system failure. Although such infections can occur in healthy hosts, the most serious cases are in immunocompromised individuals and those who have experienced a mild to severe injury to the infected site. Infections acquired from wound infections have a 20% to 30% fatality rate. One such case involved a fatal episode of multiple organ dysfunction, only 7 days after a 58-year-old Canadian patient developed septicemia with *V. vulnificus* after merely handling raw tilapia fish he had purchased for dinner.

Vibrio alginolyticus

Of the four major *Vibrio* spp. likely to be encountered in the clinical laboratory, *V. alginolyticus* is the least pathogenic for humans but is frequently isolated in clinical samples in the United States. It is a common inhabitant of marine environments and is a strict halophile, requiring at least 1% NaCl; it is able to tolerate up to 10% NaCl. Almost all isolates originate from extraintestinal sources, such as eye and ear infections or wound and burn infections. The organism can be an occupational hazard for people in constant contact with seawater, such as fishermen or sailors.

Laboratory diagnosis

Specimen collection and transport

Patients' history, including travel, underlying health conditions, recent consumption of seafood or contact with marine water, and gastroenteritis with cholera-like or rice-water stools, is important in diagnosing vibriosis. Vibrios are not fastidious, and only a few special collection and processing procedures are necessary to ensure the recovery from clinical material. Stool specimens should be collected as early as possible in the course of the illness and preferably before the administration of antimicrobial agents. Whenever possible, body fluids, pus, or tissues should be submitted, but swabs are acceptable if they are transported in an appropriate holding medium, such as Cary-Blair, to prevent desiccation. Buffered glycerol saline is not recommended as a transport or holding medium because glycerol is toxic for vibrios. Strips of blotting paper soaked in liquid stool and placed in airtight plastic bags with a few drops of saline to maintain moisture are considered viable specimens for up to 5 weeks.

Culture media

The salt concentration (0.5%) in most commonly used laboratory media, such as nutrient agar or sheep blood agar (SBA), is sufficient to support the growth of many vibrios. On SBA or chocolate (CHOC) agar, vibrios produce medium to large colonies that appear smooth, opaque, and iridescent with a greenish hue. The SBA plate should also be examined for the presence of α - or β -hemolysis. On MAC agar, the pathogenic vibrios usually grow as nonlactose fermenters. However, lactose-fermenting species such as *V. vulnificus* may be overlooked and incorrectly considered to be members of the order Enterobacterales, such as *Escherichia coli*. It is therefore imperative to determine the oxidase activity of any suspicious *Vibrio*-like colony. This can be accomplished by directly testing colonies from SBA or CHOC agar plates with oxidase

Case check 20.1

The patient in the Case in Point had a typical case history and clinical signs and symptoms of *V. vulnificus* infection. The patient suffered from posthepatic cirrhosis, a predisposing factor. In addition, he had suffered a minor wound after handling shellfish that rapidly developed into septic shock.

Fig. 20.4 *Vibrio cholerae* on thiosulfate citrate bile salt sucrose agar. (Courtesy S.W. Joseph.)

reagent or by subculturing any suspicious, lactose-fermenting colonies on MAC to an SBA plate for next-day testing. This is necessary because lactose-positive colonies from selective differential media, such as MAC agar, can give false-positive oxidase reactions.

If a selective medium is warranted because of the clinical history (exposure to seafood or seawater) or for geographic reasons (coastal area resident or recent foreign travel), TCBS agar is recommended. It differentiates sucrose-fermenting (yellow colonies) species (Fig. 20.4), such as *V. cholerae*, *V. alginolyticus*, *V. fluvialis*, *V. furnissii*, *V. cincinnatiensis*, *V. metschnikovii*, and some *V. vulnificus* strains, from the nonsucrose-fermenting (green) species, such as *V. mimicus*, *V. parahaemolyticus*, *P. damsela*, and most *V. vulnificus* strains. About 50% of *V. harveyi* isolates are sucrose-positive. Although TCBS generally inhibits all other organisms, it should be monitored with stringent quality control measures. There is great variation among different lots in regard to performance, and not all *Vibrio* spp. grow on TCBS, especially *Grimontia* (formerly *Vibrio*) *hollisae*.

If an enrichment procedure is desired to enhance isolation of vibrios, alkaline peptone water with 1% NaCl (pH 8.5) can be inoculated (at least 20 mL) and incubated for 5 to 8 hours at 35° C then subcultured at 6 hours and 18 hours onto TCBS medium. CHROMagar *Vibrio* (CHROMagar Microbiology, Paris) for the isolation and identification of *V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus* is available and can be used in

detecting these species in environmental samples and seafood. *Vibrio* colonies appear from white to pale blue to violet in color.

Presumptive identification

Several key tests can aid in the initial identification of a *Vibrio* isolate. Vibrios can be easily confused with other genera, including *Aeromonas*, *Plesiomonas*, *Pseudomonas*, and members of the order Enterobacterales. Their general susceptibility to the vibriostatic agent O/129 (150 µg) and positive string test distinguishes them from *Aeromonas*. Inability to ferment inositol (except for *V. cincinnatiensis* and some strains of *V. metschnikovii*) separates them from *Plesiomonas*. Their positive oxidase reaction (except for *V. metschnikovii*) separates them from the Enterobacterales (excluding *Plesiomonas shigelloides*), and carbohydrate fermentation metabolism separates them from the oxidative *Pseudomonas*.

Definitive identification

Numerous useful biochemical tests aid in the definitive identification of most isolates to the species level. Table 20.3 outlines 8 key differential tests to divide the 10 most clinically significant *Vibrio* spp. into 6 groups as an initial identification step. Some additional tests necessary to identify eight clinical *Vibrio* spp. from groups 1, 5, and 6 are summarized in Table 20.4. It is important to note that with the halophilic vibrios, it often is necessary to add at least 1% NaCl to most biochemical media to obtain reliable reaction results.

Rapid and semiautomated identification systems

Although rapid and semiautomated identification systems contain databases of the more commonly encountered clinical vibrios, they generally are inadequate for accurate identification of these species, particularly those that are less commonly encountered. The inoculating suspensions should contain at least 0.85% NaCl, such as that found with the API-20E identification strips (bioMérieux Vitek, Hazelwood, MO). Even then, the halophilic species might grow poorly, if at all, and they often are confused with other genera, such as *Aeromonas*. Identification using commercial systems remains challenging. One study evaluated six commercially available systems that resulted in identification of only 63% to 81% of organisms at the species level. Most authorities advocate identification with conventional biochemicals, supplemented with additional NaCl, if warranted; alternatively, the rapid system identification should be confirmed at a reference laboratory or state public health department laboratory.

The use of 16S ribosomal ribonucleic acid (rRNA) sequencing alone is less than ideal because of small differences in sequences and polymorphisms among the various species. As databases are developed, matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry might become a rapid, cost-effective means of identification. This method has demonstrated accurate identification of *V. parahaemolyticus*.

Serology

Agglutination, vibriocidal, or antitoxin tests performed on acute and convalescent sera are considered reliable methods for testing vibrios serologically. In any case, all isolates

Case check 20.2

It is important to use selective media and key biochemical reactions to differentiate *Vibrio* from *Vibrio*-like organisms. Key biochemical tests to differentiate various *Vibrio* spp. include reaction on TCBS, agent O/129 susceptibility or resistance, the string test, and growth in different concentrations of NaCl. The Case in Point uses the results obtained from these reactions to identify the responsible organism.

with a presumptive biochemical identification of *V. cholerae* should be promptly reported to the appropriate public health authorities, and the isolate should be forwarded to the health department or a reference laboratory for serotyping.

Antimicrobial susceptibility

Both Mueller-Hinton agar and broth contain sufficient salt to support the growth of *Vibrio* spp. most often isolated from clinical specimens. The recommended antimicrobial susceptibility testing methods are standardized disk diffusion (Kirby-Bauer) or dilution susceptibility testing methods. The Clinical and Laboratory Standards Institute (CLSI) has interpretive guidelines only for *V. cholerae* limited to ampicillin, tetracyclines, folate pathway inhibitors, and chloramphenicol. In general, most strains of *V. cholerae* are susceptible to doxycycline or ciprofloxacin. Increased resistance from the acquisition of plasmids is relatively uncommon in the United States, but there are reports of multiple resistant strains from Asia and Africa.

Because most vibrios grow rather rapidly and are similar to enteric bacteria in many ways, it is often useful for a first approximation to use the interpretive guidelines for the Enterobacterales when testing *Vibrio* isolates other than *V. cholerae* for agents not currently covered by the CLSI documents M100 (*V. cholerae*) and M45 (other species). In general, fluoroquinolones alone or the synergistic combination of ciprofloxacin and cefotaxime display excellent in vitro activity against *V. vulnificus* strains. Most vibrios are also susceptible to gentamicin, tetracyclines, chloramphenicol (except *P. damsela*), monobactams, carbapenems, and fluoroquinolones.

Aeromonas

The genus *Aeromonas* consists of ubiquitous, oxidase-positive, glucose-fermenting, gram-negative rods (Fig. 20.5) that are widely distributed in freshwater, estuarine, and marine environments worldwide. They are frequently isolated from retail produce sources and animal meat products. Aeromonads are responsible for a diverse spectrum of disease syndromes in warm- and cold-blooded animals, including fish, reptiles, amphibians, mammals, and humans.

Fig. 20.5 Microscopic morphology of *Aeromonas* on Gram-stained smear (×1000). (Courtesy J. Michael Janda.)

Previously, the genus *Aeromonas* resided in the family Vibrionaceae. However, phylogenetic evidence from molecular studies resulted in the proposal of a separate family, Aeromonadaceae. Currently, there are 36 species of aeromonads characterized in the latest edition of *Bergey's manual of systematic bacteriology*. Of those species, at least 19 have been identified as emerging pathogens in humans. A recent study, however, reported most human pathogens (95.4%) were identified from only four species: *Aeromonas caviae* (37.26%), *Aeromonas dhakensis* (23.49%), *Aeromonas veronii* (21.54%), and *Aeromonas hydrophila* (13.07%). In the United States, aeromonads have a seasonal pattern of increased isolation from May to October, reflecting their increased numbers in aquatic environments in the warmer months.

General characteristics

Aeromonads are straight rods (1.0 to 3.5 μm long by 0.3 to 1.0 μm wide). In the mid 1970s, they were classified into one of two groups, the mesophilic group that causes several human infections (motile organisms with optimal growth around 37° C) or the psychrophilic group that is linked to fish diseases

(nonmotile strains with optimal growth around 22° C). The mesophilic group consists of three different complexes or groups of species. One is the *A. hydrophila* complex, which includes *A. hydrophila* subsp. *hydrophila*, *A. hydrophila* subsp. *ranae*, *A. bestiarum*, and *A. dhakensis*. Another is the *A. veronii* complex, which includes *A. veronii* biovar *sobria* (formerly misidentified as *A. sobria*), *A. veronii* biovar *veronii*, *A. jandaei*, *A. trota*, *A. schubertii*, *A. diversa*, and *A. encheleia*. The last mesophilic complex is the *A. caviae* complex, which includes the species *A. caviae*, *A. media*, *A. rivipollensis*, and *A. eucrenophila*. These organisms are considered mesophiles because they grow well at 37° C. They are all motile by means of a single polar flagellum.

The psychrophilic group consists of only one species, *A. salmonicida*, which is a fish pathogen with several subspecies. This organism is nonmotile and grows best at 22° to 25° C. Psychrophilic nonmotile strains are not considered human pathogens. All aeromonads, in general, can typically grow from 10° to 42° C.

Clinical manifestations

Intestinal infections

The aeromonads are recognized as enteric pathogens, albeit not in the same manner as the more common enteric pathogens *Salmonella*, *Shigella*, and *V. cholerae*. The level and pattern of virulence is more like the multifactorial patterns of the various *E. coli* subgroups associated with enteric disease (e.g., enterotoxigenic *E. coli*, enterohemorrhagic *E. coli*). Therefore screening of stool specimens for the presence of these organisms, followed by further identification to the species level, is appropriate. This is especially true in cases of pediatric diarrhea or in any immunocompromised individual.

The medical history of patients displaying diarrhea and harboring aeromonads often, but not always, involves aquatic exposure, such as an association with untreated groundwater or consumption of seafood, particularly raw oysters or clams. Infections have also been linked to fresh produce and dairy products. Five diarrheal presentations are observed in patients in whom *Aeromonas* has been isolated from their stools:

1. Acute, secretory diarrhea often accompanied by vomiting
2. An acute, dysenteric form of diarrhea (similar to shigellosis) with blood and mucus
3. Chronic diarrhea usually lasting more than 10 days
4. A cholera-like disease, including rice-water stools
5. The nebulous syndrome commonly referred to as *traveler's diarrhea* (similar to enterotoxigenic *E. coli*). Most cases are self-limiting, but in pediatric, geriatric, and immunocompromised populations, supportive therapy and antimicrobials are often indicated.

A. caviae is the species most frequently associated with gastrointestinal infections, especially in neonate and pediatric populations; it has been associated with inflammatory bowel disease. Other species associated with diarrhea include *A. hydrophila* and *A. veronii* (biovars *sobria* and *veronii*). More serious complications, usually from infections with *A. hydrophila* and *A. veronii* biovar *sobria*, include hemolytic uremic syndrome or kidney disease that might require kidney transplantation. *A. veronii* biovar *sobria* has also been

linked to cholera-like disease characterized by abdominal pain, fever, and nausea.

Extraintestinal infections

Aeromonads are also responsible for extraintestinal infections; septicemia and wound infections are the most common. They have also been implicated in cases of meningitis, osteomyelitis, pelvic abscesses, otitis, cystitis, endocarditis, peritonitis, cholecystitis, keratitis associated with contact lens wear, and endophthalmitis in healthy and immunocompromised individuals. Wound infection invariably involves a recent traumatic aquatic exposure, such as a boating or fishing accident, and generally occurs on the extremities. The most common presentation is cellulitis, although there have been a few cases of myonecrosis and necrotizing fasciitis and even a rare case of ecthyma gangrenosum associated with sepsis. Aeromonad wound isolates are predominantly *A. hydrophila* subsp. *hydrophila*, *A. veronii*, and *A. dhakensis*. Among the survivors of the 2004 tsunami in southern Thailand, *Aeromonas* spp. were the most common cause of skin and soft tissue infections. Elevated numbers of *Aeromonas* spp. were recorded in flood water samples in New Orleans after Hurricane Katrina in 2005.

An association between *A. veronii* biovar *sobria* and surgical wound infections involving the use of leeches for medicinal therapy after plastic surgery to relieve venous congestion has been noted. These patients can develop serious aeromonad wound infections. It appears that the leech *Hirudo medicinalis* has a symbiotic relationship with this aeromonad species within its gut, wherein the organisms aid in the enzymatic digestion of the blood ingested by the leech.

Aeromonad sepsis is one of the most invasive type of *Aeromonas* infection and similarly has a strong association with the species *A. veronii* biovar *sobria*, *A. caviae*, *A. dhakensis*, and *A. hydrophila*. Such patients are most likely to be immunocompromised and have a history of liver disease or dysfunction, hematologic malignancies, hepatobiliary disorders, or traumatic injuries. Also at high risk are individuals with leukemia, lymphoma, or myeloma. Although the original source of infection is often unknown, it is surmised that it is the gastrointestinal, biliary, or even more rarely, respiratory tract.

Laboratory diagnosis

Culture media

Aeromonads grow readily on most media used for routine and stool cultures. After 24-hour incubation at 35° C, aeromonads appear as large, round, raised, opaque colonies with an entire edge and a smooth, often mucoid, surface. Frequently, an extremely strong odor is present, and pigmentation ranges from translucent and white to buff-colored. Hemolysis is variable on SBA, but most major clinical species, such as *A. hydrophila*, *A. veronii* biovar *sobria*, and *A. jandaei*, display strong β -hemolysis (Fig. 20.6). In addition, the most commonly isolated species, *A. caviae*, has been showing increasing incidence of β -hemolysis on SBA. Although aeromonads grow on almost all enteric media, they often are overlooked on MAC agar, especially in stool cultures, because a number of aeromonads ferment lactose. This is of particular

Fig. 20.6 *Aeromonas hydrophila* exhibiting β -hemolysis on sheep blood agar. (Courtesy A. J. Horneman.)

Fig. 20.7 *Aeromonas caviae* exhibiting lactose fermentation on MacConkey agar. (Courtesy A. J. Horneman.)

concern because the most commonly isolated species, especially in pediatric cases of diarrhea, is the lactose-fermenting *A. caviae*. This particular species is generally overlooked as normal biota *E. coli* (Fig. 20.7).

The combined use of SBA with 20 μ g of ampicillin per milliliter and a modified cefsulodin-irgasin-novobiocin (CIN) plate, with only 4 μ g of cefsulodin instead of 15 μ g, might yield the highest recovery of aeromonads. However, the incorporation of ampicillin in the blood agar may inhibit some *A. caviae* as well as all *A. trota* strains because the hallmark feature of *A. trota* is its unusual universal susceptibility to ampicillin. Therefore SBA without ampicillin is preferred. On the standard CIN formulation for enteric *Yersinia* or the

modified CIN media, *Aeromonas* will form pink-centered colonies from the fermentation of mannitol, with an uneven, clear apron resembling *Yersinia enterocolitica*. However, an oxidase test performed on SBA colonies will easily separate the oxidase-positive aeromonads from the oxidase-negative yersinias. The use of an enrichment broth is generally not considered necessary. However, if such a medium is warranted for detecting chronic cases or asymptomatic carriers, alkaline peptone water is recommended. This can be inoculated, incubated overnight at 35° C, and subsequently subcultured to appropriate plate media.

Presumptive identification

An important screening procedure for aeromonads is to perform an oxidase test and a spot indole test on suspicious colonies on SBA, especially β -hemolytic colonies. A positive oxidase test distinguishes aeromonads from the order Enterobacterales (except for *Plesiomonas shigelloides*), and most clinically relevant aeromonads are indole-positive. The presence and type of hemolysis among multiple aeromonad colony types in a single culture often are the only clues to an infection involving more than one species of *Aeromonas*.

Members of the genera *Vibrio*, *Aeromonas*, and *Plesiomonas* have many similar characteristics. See Table 20.2 for key tests to help separate these three genera. The best tests to distinguish the aeromonads from *Vibrio* spp. are the string test (usually negative for aeromonads and positive for vibrios) and testing for sensitivity to O/129 (aeromonads are usually resistant, and most vibrios are susceptible; see Fig. 20.2).

A test to separate aeromonads and plesiomonads from most vibrios is determining the ability to grow in the presence of NaCl. Aeromonads and plesiomonads grow well in nutrient broth with 0% NaCl, but not in 6% NaCl. Conversely, most vibrios, specifically the halophilic species, cannot grow in 0% NaCl but thrive in 6% NaCl and even higher concentrations of NaCl (Fig. 20.8). However, because *V. cholerae* and *V. mimicus* are nonhalophilic and grow well without additional salt, any salt tolerance test must be used in conjunction with the string test and O/129 disk to distinguish aeromonads from this major pandemic cholera species and the less common, sucrose-negative *V. mimicus*. Fermentation of inositol can be used for separating aeromonads from plesiomonads, in which aeromonads are negative and plesiomonads are positive. Finally, the ability to ferment glucose, with or without the production of gas, distinguishes *Aeromonas* from oxidase-positive, nonfermenting *Pseudomonas* isolates.

Definitive identification

Nucleic acid amplification tests (NAATs) are the most accurate in the identification of aeromonads. Definitive identification is also accomplished with a small number of conventional and readily available biochemical tests, including the API-20E test strip (bioMérieux); however, limitations in identifying aeromonads to the species level exist with most commercially available systems. MALDI-TOF mass spectrometry accurately identifies most aeromonads to the genus level, but identification to the species level is limited. Two FDA-cleared systems are available: the MALDI Biotyper

system (Bruker, Billerica, MA) and the IVD 3.0 Vitek MS (bioMérieux), but again, limitations occur in both systems because of limited database content. Typing systems such as PFGE and PCR-based techniques are also available for identification. Serologic assays (i.e., immunoblotting and

enzyme-linked immunosorbent assay [ELISA]) yield low sensitivity and are not readily dependable.

Conventional biochemical tests as shown in Table 20.5 are useful in the identification of aeromonads to the species level; however, they have the longest turnaround time of all methods described with the lowest performance.

Antimicrobial susceptibility

Although most cases of *Aeromonas*-associated gastroenteritis are self-limiting, antimicrobial therapy is often indicated. It is always warranted in wound infections and septicemia. As a genus, aeromonads are almost uniformly resistant to penicillin, ampicillin, and cephalothin or cefazolin, except for the susceptibility of *A. trota* to ampicillin. Aeromonads are variable with regard to ticarcillin or piperacillin and cefoxitin.

Thus far, *A. veronii* biovar *veronii* isolates still appear to be susceptible to cephalothin, but only *A. veronii* biovar *veronii* is 100% susceptible to cefoxitin. Otherwise, aeromonads are generally susceptible to trimethoprim-sulfamethoxazole, aminoglycosides, and quinolones, although *A. veronii* biovar *veronii* is moderately resistant to tobramycin. It should be noted that there have been reports of a case of sepsis with an extended-spectrum β -lactamase (ESBL)-producing *A. hydrophila* and a case of necrotizing fasciitis, with the probable in vivo transfer of a TEM-24 plasmid-borne gene coding for an ESBL from *Enterobacter aerogenes*.

CLSI antimicrobial susceptibility studies should always be determined by the standard Kirby-Bauer disk diffusion method. This is because of possible serious discrepancies in β -lactamase detection by rapid minimal inhibitory concentration methods that would directly affect the proper treatment of aeromonad infections.

Fig. 20.8 Both *Aeromonas* and *Plesiomonas* spp. will grow in nutrient broth with 0% NaCl (left), whereas neither will grow in nutrient broth with 6% NaCl (right). (Courtesy A. J. Horneman.)

Case check 20.3

Although *Aeromonas* and *Plesiomonas* are similar to *Vibrio* spp., the key biochemical results used in the Case in Point were able to rule out *Aeromonas* and *Plesiomonas* as the infecting organism and aided in definitively identifying *Vibrio* as the pathogen causing the disease.

Campylobacter and Campylobacter-like species

Campylobacter and *Campylobacter*-like species, which include *Helicobacter*, *Arcobacter*, and *Wolinella*, have undergone changes in taxonomy. Campylobacters were formerly classified with the vibrios because of their positive oxidase and characteristic microscopic morphology, but DNA homology studies showed that *Campylobacter* spp. do not belong with the vibrios. In addition, unlike the vibrios, which are fermentative, most campylobacters are asaccharolytic. The genus *Campylobacter* belongs to the family Campylobacteraceae, whereas the genera *Helicobacter* and *Wolinella* are members of the family Helicobacteriaceae. The genus *Acrobacter* is in the family Arcobacteraceae.

Based on rRNA sequence studies, *Wolinella recta* and *Wolinella curva* were transferred to the genus *Campylobacter* as *C. rectus* and *C. curvus*. Although they may appear to be strict anaerobes, they have been grown in a **microaerophilic** environment. Microaerophilic organisms, such as *Campylobacter*, require oxygen, but at a concentration less than that of room air; 5% is normally optimal. To date, there are 43 species of *Campylobacter*. There are 39 species of *Helicobacter*, most of which colonize the stomachs of mammals.

Epidemiology

Campylobacter spp. have been known to cause abortion in domestic animals, such as cattle, sheep, and swine, and are primarily zoonotic organisms. Although these organisms were suspected of causing human infections earlier, campylobacters were not established as human pathogens until sensitive isolation procedures and media were developed. Today, the most common cause of bacterial gastroenteritis worldwide is *Campylobacter jejuni*. The transmission of campylobacteriosis has been attributed to direct contact with animals and handling infected pets, such as dogs, cats, and birds, and indirect contact by consumption of contaminated water and dairy products and improperly cooked poultry. Person-to-person transmission has been reported, and some *Campylobacter* spp. are also sexually transmitted.

In 2019, the Foodborne Diseases Active Surveillance Network estimated that approximately 20 cases of campylobacteriosis are diagnosed every year for each 100,000 people in the population. The CDC reported 236 foodborne outbreaks of *Campylobacter* from 2010 to 2017, accounting for 2381 illnesses. Poultry, raw milk, and untreated water were the sources most often identified. Because of unreported or misdiagnosed cases, it is believed campylobacteriosis affects over 1.5 million individuals each year. The populations that most often manifest the disease include infants and young adults, although all age groups are at risk. In addition to

C. jejuni, *C. coli* and *C. lari* also cause gastrointestinal disease (the enteric campylobacters).

Campylobacter fetus subsp. *fetus* has been isolated most frequently from blood cultures and is rarely associated with gastrointestinal illness. Most infections occur in immunocompromised individuals, during pregnancy, and in older adults. *Arcobacter* spp. have been isolated from a variety of animals: cattle, pigs, sheep, birds, etc. In humans, they have been linked to bacteremia, endocarditis, peritonitis, and diarrhea. Table 20.6 summarizes the clinical significance of *Campylobacter*, *Arcobacter*, and *Helicobacter* organisms.

Table 20.6 Clinically significant *Campylobacter* species and *Campylobacter*-like organisms

Species	Clinical Significance
<i>Arcobacter butzleri</i>	Associated with diarrheal disease and bacteremia in humans and in children with recurring gastrointestinal illness (abdominal cramps), endocarditis, and peritonitis
<i>Arcobacter cryaerophilus</i>	Isolated from cases of human bacteremia and diarrhea
<i>Arcobacter skirrowii</i>	Gastroenteritis
<i>Campylobacter jejuni</i>	Most common cause of bacterial diarrhea worldwide
<i>Campylobacter coli</i>	Gastroenteritis, bacteremia in immunocompromised patients
<i>Campylobacter fetus</i> subsp. <i>fetus</i>	Bacteremia in immunocompromised patients and extraintestinal infections during pregnancy
<i>Campylobacter concisus</i>	Involved in periodontal disease; has also been recovered from individuals with gastrointestinal illness
<i>Campylobacter curvus</i>	Gastroenteritis, periodontal disease
<i>Campylobacter gracilis</i>	Bacteremia, soft tissue abscesses
<i>Campylobacter hyointestinalis</i>	Gastroenteritis
<i>Campylobacter lari</i>	Enteritis very similar to that caused by <i>Campylobacter jejuni</i> , also septicemia
<i>Campylobacter rectus</i>	Gastroenteritis; associated with periodontal disease
<i>Campylobacter sputorum</i> biovar <i>sputorum</i>	Lung, axillary, groin abscesses
<i>Helicobacter pylori</i>	Common cause of duodenal ulcers and type B gastritis; risk factor in gastric carcinoma, and MALT lymphoma
<i>Helicobacter bilis</i>	Bacteremia, sepsis
<i>Helicobacter canadensis</i>	Gastroenteritis
<i>Helicobacter cinaedi</i>	Colitis, cellulitis, and sepsis
<i>Helicobacter felis</i>	Gastritis and ulcers
<i>Helicobacter fennelliae</i>	Colitis, sepsis

Helicobacter pylori is strongly associated with gastric, peptic, and duodenal ulcers and with gastrointestinal carcinoma. *H. pylori* has been identified in as many as 80% of gastric ulcer patients. Although the organism was previously found in human gastric tissue, it was difficult to assess their significance because the samples were taken at autopsy. It is estimated that 50% of the population worldwide is infected with *H. pylori*. In developing countries in Africa, Asia, and South America, the incidence is reported to be as high as 80% to 90%. This higher incidence is attributed to poor sanitary conditions, and it appears that infection occurs early in life. Some data suggest human-to-human transmission and the possibility of human reservoirs. Although it is not conclusively proven, fresh groundwater is the likely source of many infections.

Clinical manifestations

Campylobacter

Several *Campylobacter* spp. have been implicated in human infection, the most common being *C. jejuni*, *C. coli*, *C. fetus* subsp. *fetus*, *C. lari*, and *C. upsaliensis*. Patients infected with *C. jejuni* present with a diarrheal disease that begins with mild abdominal pain within 2 to 10 days after ingestion of the organism. Cramps and diarrhea (with or without blood/fecal white cells) often follow the initial signs and symptoms. Patients may experience fever and chills and, rarely, nausea and vomiting. In most patients, the illness is self-limiting and usually resolves in 2 to 6 days. Untreated patients can remain carriers for several months. Other enteric *Campylobacter* infections (those caused by *C. coli*, *C. lari*, and *C. upsaliensis*) have similar clinical manifestations.

The *C. fetus* species contains three subspecies, *C. fetus* subsp. *fetus*, *C. fetus* subsp. *venerealis*, and *C. fetus* subsp. *testudinum*. *C. fetus* subsp. *fetus* is primarily linked to bacteremia in pregnant women and patients who are immunocompromised. It is also associated with gastroenteritis. However, cases are underreported because this species does not grow at 42° C, the temperature stool cultures are generally incubated to recover the enteric campylobacters.

Strong evidence suggests that *Campylobacter* infection plays a role in GBS, an autoimmune disorder characterized by acute paralysis caused by damage to the peripheral nervous system. Many patients with GBS test positive for antibodies to *Campylobacter*, with an estimated 1 in 1000 individuals diagnosed following a *Campylobacter* infection. It is believed that antibodies produced during a *Campylobacter* infection bind to gangliosides found on peripheral nerves. Cross-reactivity with these nerve cells in an autoimmune response may be responsible for this debilitating nerve disorder.

Helicobacter pylori

H. pylori has been primarily linked to gastric infections and peptic ulcer disease. Once acquired, *H. pylori* colonizes the stomach for a long time and can cause a low-grade inflammatory process, producing a chronic superficial gastritis. Although it does not invade the gastric epithelium, the infection is recognized by the host immune system, which initiates an antibody response. The antibodies produced are not protective, however.

H. pylori is also recognized as a major cause of **type B gastritis**, a chronic condition formerly associated primarily with stress and chemical irritants. In addition, there is a strong association between long-term *H. pylori* infection and gastric cancer. *H. pylori* causes a rare stomach cancer called *mucosa-associated lymphoid tissue* (MALT). This rare type of cancer is the only cancer that may be cured with antimicrobial agents. Other species of helicobacters, including *H. cinaedi* and *H. fennelliae*, have been associated with human gastroenteritis and bacteremia, generally in immunocompromised patients. In addition, enterohepatic helicobacters infect humans and inhabit the intestinal and hepatobiliary tracts of various mammals and birds. It is believed that transmission of these enterohepatic species occurs from animals to humans.

Laboratory diagnosis

Specimen collection and transport

C. fetus subsp. *fetus* can be recovered in several routine blood culture media and is often associated with bacteremia and extraintestinal infections. *Campylobacter* spp. that cause enteric illness are isolated from stool samples and rectal swabs, the less preferred specimen. If a delay in processing the stool specimen is anticipated, it can be placed in a transport medium such as Cary-Blair to maintain the viability of the organisms, modified Cary-Blair, or Fecal Enteric Plus. A common stool transport medium, buffered glycerol saline, is toxic to enteric campylobacters and should therefore be avoided.

H. pylori can be recovered from gastric biopsy materials. Samples must be transported quickly to the laboratory. Stuart medium can be used to maintain the viability of the organisms if a delay in processing is anticipated. Tissue samples may also be placed in cysteine-Brucella broth with 20% glycerol and frozen at -70° C or Portagerm pylori media (bioMérieux).

Culture media

An enriched selective agar, *Campylobacter* blood agar (*Campy* blood agar) is a commonly used medium to isolate *C. jejuni* and other enteric campylobacters. This commercially available medium contains Brucella agar base, 10% sheep red blood cells, and a combination of antimicrobials: vancomycin, trimethoprim, polymyxin B, amphotericin B, and cephalothin. Other selective media that have been successful in recovering *Campylobacter* spp. are Butzler medium and Skirrow's medium. Table 20.7 shows the composition of each of these selective media.

Campy-CVA (cefoperazone-vancomycin-amphotericin B) medium has been reported to provide better suppression of fecal biota, even when this medium is incubated at 37° C. Incubation at 37° C allows the recovery of *Campylobacter* spp. that are inhibited at 42° C. *C. fetus* subsp. *fetus*, *C. rectus*, and *C. curvus* can be isolated using routine culture media. Charcoal-based, blood-free media, such as charcoal cefoperazone deoxycholate agar (CCDA) and charcoal-based selective media (CSM), are also available. Studies have shown that blood-free, charcoal-containing selective medium is superior in isolating *Campylobacter* spp. compared to media containing blood. A combination of media that contains either CCDA or CSM can achieve the highest yield of *Campylobacter* spp.

Table 20.7 Selective media for the cultivation of *Campylobacter* species

Medium	Base	Antimicrobial agent
Campy blood agar plate	Brucella agar	Vancomycin
		Trimethoprim
	10% sheep red blood cells	Polymyxin B
		Amphotericin B
Skirrow's	Heart infusion	Cephalothin
		Vancomycin
	Lysed, defibrinated horse red blood cells	Trimethoprim
		Polymyxin B
Butzler	Columbia blood	Bacitracin
		Novobiocin
	Horse blood, defibrinated	Cycloheximide
		Colistin
CCDA	Nutrient agar	Cefazolin
		Cefoperazone
	Charcoal	Amphotericin B
	Sodium desoxycholate	

CCDA, Charcoal cefoperazone deoxycholate agar (Becton Dickinson, Franklin Lakes, NJ).

in stool samples. To recover *H. pylori*, a combination of a nonselective medium, such as CHOC agar or Brucella agar with 5% horse red blood cells, and a selective medium, such as Skirrow's agar or Wilkins-Chalgren agar, may be used. It is important that the inoculated medium be fresh and moist and that the culture be incubated in a microaerophilic environment, with increased humidity.

Incubation

There is a double purpose for incubating stool cultures at 42° C to recover *C. jejuni*. First, *C. jejuni* and other enteric campylobacters grow optimally at 42° C. Second, growth of colon microbiota is inhibited at this higher temperature. *C. fetus* subsp. *fetus*, on the other hand, is a rare stool isolate, and growth is suppressed at 42° C; therefore to isolate this organism, media should be incubated at 37° C.

Enteric *Campylobacter* and *Helicobacter* spp. require a microaerophilic and capnophilic environment. The ideal atmospheric environment for these organisms is a gas mixture of 5% O₂, 10% CO₂, and 85% N₂ for *Campylobacter* spp. and 4% O₂, 5% CO₂, 5% H₂, and 86% N₂ for *Helicobacter* spp. Except for *C. rectus* and *C. curvus*, a strict anaerobic environment does not support the growth of most *Campylobacter* spp. Several methods can be used to obtain the required environment for campylobacters. With the GasPak EZ Gas Generating Container System (BD Diagnostic Systems, Sparks, MD), specimen plates along with a sachet are placed into a clear plastic incubation container, sealed, and incubated at the appropriate temperature. The sachet is activated on exposure to air once the foil pouch is removed. The GasPak

Fig. 20.9 Microscopic morphology of *Campylobacter* on Gram-stained smear (×1000).

EZ Gas Generating Pouch System can hold up to four plates but requires at least two plates per resealable pouch. One sachet is added to each pouch and is activated on exposure to air, similar to the previous procedure. For optimal results, a paper towel or moistened cotton ball with 5mL of water should be placed inside the pouch. The pouch is sealed by closing the zipper part of the pouch and then incubated at the appropriate temperature.

Presumptive identification

Microscopic morphology

Campylobacter spp. are curved, non-spore-forming, gram-negative rods that measure approximately 0.2 to 0.9 μm × 0.5 to 5.0 μm (Fig. 20.9). Enteric campylobacters may appear as long spirals or S- or seagull-wing shapes. These organisms may appear as coccobacilli in smears prepared from older cultures. On Gram-stained smears, these organisms stain poorly. For better visualization, carbol-fuchsin is recommended as a counterstain; if safranin is used, counterstaining should be extended to 2 to 3 minutes.

Campylobacter spp. exhibit a characteristic “darting” motility on hanging drop preparations or when visualized under phase-contrast microscopy. It should be noted that the sensitivity using phase-contrast microscopy to observe motile organisms has not been widely studied; therefore considerable skill is needed to identify these organisms. To observe the typical motility, organisms should be suspended in *Brucella* or tryptic soy broth. Distilled water and saline seem to inhibit motility.

Arcobacter spp. have a microscopic morphology similar to that of *Campylobacter* spp. Unlike the single polar flagellum of campylobacters, *Helicobacter* spp. have either a single polar flagellum or multiple flagella at one pole.

Colony morphology

The typical colony morphology of *C. jejuni* and other enteric campylobacters is moist, runny looking, and spreading. Colonies are usually nonhemolytic; some are round and raised, and others may be flat. *C. fetus* subsp. *fetus* produces smooth, convex, translucent colonies. A tan or slightly pink

From Nachamkin, I. (2019). *Campylobacter* and *Arcobacter*. In K. C. Carroll, et al. (Eds.), *Manual of clinical microbiology* (12th ed., p. 1032). Washington, DC: ASM Press; and Couturier, M. R. (2019). *Helicobacter*. In K. C. Carroll, et al. (Eds.), *Manual of clinical microbiology* (12th ed., p. 1046). Washington, DC: ASM Press.

coloration is observed in some enteric campylobacter colonies. Other *Campylobacter* species produce colonies similar to those of *C. jejuni*. Although most do not produce pigment, *C. mucosalis* and *C. hyointestinalis* can produce a dirty yellow pigment.

Definitive identification

Isolates from stool specimens and rectal swabs can be presumptively identified as *Campylobacter* spp. by a positive-oxidase, the characteristic Gram-stained microscopic morphology, and the characteristic motility. The microscopic morphology is important because it differentiates *Campylobacter* from other bacteria, such as *Aeromonas* and *Pseudomonas*, which are oxidase-positive and can grow at 42° C in a microaerophilic environment. A positive hippurate hydrolysis is an important characteristic for the identification of *C. jejuni*. Table 20.8 lists the biochemical tests most useful for definitively identifying the most commonly encountered *Campylobacter*, *Arcobacter*, and *Helicobacter* species. *Campylobacter* identification can be achieved using

fecal antigen detection methods and NAATs, including real-time PCR, Prodesse ProGastro SSCS (Hologic GenProbe, San Diego, CA), Luminex xTAG GPP (Luminex Molecular Diagnostics), Verigene EP (Luminex Molecular Diagnostics), BioFire Film Array GP (bioMérieux), and BD Max EB (Becton Dickinson, Franklin Lakes, NJ) assays. Typing systems such as PFGE and multilocus sequence typing (MLST) are also available. MALDI-TOF mass spectrometry can be used to identify common and uncommon species of *Campylobacter*; however, growth conditions must be optimized for successful identification of *Campylobacter* spp.

Helicobacter infections usually are identified by nonculture methods. *H. pylori* can be presumptively identified in a gastric biopsy specimen by a rapid urease test (Fig. 20.10). The collected tissue sample is placed onto Christensen's urea medium and incubated at 37° C for 2 hours. A color change suggests the presence of *H. pylori*. Other rapid, commercially available tests include the CLOtest Rapid Urease Test (Kimberly Clark/Ballard Medical Products, Neenah, WI) and a paper strip test by PyloriTek (BARD, Murray Hill, NJ).

Fig. 20.10 Urease reactions. *Left to right*, Negative, weak positive, positive.

Urease activity can also be detected by the **urea breath test**, which is reportedly sensitive and specific and is recommended for monitoring therapy. In this test, the patient is given ^{13}C -labeled urea orally. Urea degraded by the urease activity of *H. pylori* in the stomach releases $^{13}\text{CO}_2$, which is absorbed into the bloodstream and detected in the exhaled breath by a scintillation counter. *H. pylori* infection can also be diagnosed by fecal antigen detection using enzyme immunoassay methodology, microscopic examination of stained gastric tissue, and DNA amplification tests (e.g., PCR assay).

Immunologic assays

Latex agglutination tests are available for the rapid identification of colonies of enteric campylobacters on primary isolation media. Two commercial kits are available in the United States for culture identification, Campy JCL (Scimedx, Denville, NJ) and DrySpot Campylobacter test kit (Thermo Fisher Scientific, Waltham, MA). These kits can detect the presence of *C. jejuni*, *C. coli*, *C. upsaliensis*, *C. lari*, and sometimes *C. fetus* subsp. *fetus*. However, neither system differentiates among the *Campylobacter* spp. Commercial kits are also available for detecting *Campylobacter* antigen in fecal samples.

Specific antibodies in serum can be detected by ELISA or indirect immunofluorescent assay methods. These methods have been reported to be reasonably sensitive and specific indicators of *Campylobacter* and *H. pylori* infections. Serologic testing is useful for epidemiologic studies for *Campylobacter* but is not recommended for routine diagnosis. Serologic testing measuring IgG antibodies using ELISA kits is an important screening method for the diagnosis of *H. pylori* infection.

Antimicrobial susceptibility

C. jejuni and *C. coli* exhibit variable susceptibilities to antimicrobials such as macrolides, fluoroquinolones,

aminoglycosides, chloramphenicol, and tetracycline. Both species are usually susceptible to macrolides; however, it must be noted that erythromycin resistance rates have increased and are more common in *C. coli* compared to *C. jejuni*. Most patients usually recover without antimicrobial intervention. Ciprofloxacin and other quinolones can also be used; however, ciprofloxacin resistance is high among isolates in the United States. Ampicillin, aminoglycosides, imipenem, and chloramphenicol can be used to treat systemic *C. fetus* infections.

The standard triple therapy for treating *H. pylori* infections consists of clarithromycin, either amoxicillin or metronidazole, and a proton pump inhibitor. An alternative regimen consisting of fluoroquinolone, levofloxacin, and a rifamycin (rifabutin) can be used.

POINTS TO REMEMBER

- Most species in this chapter are found in fresh, estuarine, or marine water.
- Thirteen species of *Vibrio* have been implicated in human infection, and most are agents of diarrheal disease.
- *V. cholerae* produces a powerful enterotoxin and is responsible for large numbers of epidemics and pandemics.
- Other *Vibrio* spp. are common causes of diarrheal disease related to the consumption of raw shellfish or related to aquatic wound infections with serious sequelae, such as septicemia and death.
- TCBS agar is the medium of choice to isolate and differentiate the *Vibrio* spp. This medium distinguishes sucrose-fermenting strains from nonsucrose-fermenting strains.
- *Aeromonas* spp. can cause several types of diarrhea and a variety of extraintestinal infections that can lead to septicemia, meningitis, and death.
- Human *Campylobacter* spp. are generally responsible for gastroenteritis; *C. jejuni* is one of the most common causes of bacterial diarrhea worldwide.
- Patients suffering from GBS often test positive for *Campylobacter* antibodies. GBS is believed to be an autoimmune disorder resulting from cross-reactivity of *Campylobacter* antibodies with the nerve ganglia.
- *H. pylori* is strongly associated with gastric and duodenal ulcers and has been implicated in cases of gastric carcinoma.
- *Campylobacter* and *Helicobacter* are microaerophilic, requiring oxygen at concentrations less than that found in ambient air.

LEARNING ASSESSMENT QUESTIONS

1. A gram-negative bacillus isolated from a stool specimen produces clear colonies on MacConkey agar and yellow colonies on thiosulfate citrate bile salt sucrose medium. The isolate is subcultured to a sheep blood agar plate with an O/129 disk. The isolate is sensitive to O/129 and is oxidase-positive. Which organism would you suspect?
 - a. *Vibrio parahaemolyticus*
 - b. *Vibrio cholerae*
 - c. *Plesiomonas*
 - d. *Aeromonas*

2. A patient with hemochromatosis developed septicemia after ingesting contaminated shellfish. What is the mortality rate after infection with this organism?
 - a. 20% to 30%
 - b. 30% to 40%
 - c. 40% to 50%
 - d. Above 50%
3. Which of the following genera is typically microaerophilic?
 - a. *Helicobacter*
 - b. *Aeromonas*
 - c. *Plesiomonas*
 - d. *Vibrio*
4. *Campylobacter jejuni* is most noted for causing which condition?
 - a. Wounds
 - b. Septicemia
 - c. Gastric ulcers
 - d. Gastroenteritis
5. Which of the following is a risk factor for acquiring *Vibrio alginolyticus* infection?
 - a. Farming
 - b. Hunting
 - c. Fishing or swimming in ocean water
 - d. Drinking unpasteurized milk
6. An oxidase-positive, indole-positive, β -hemolytic, gram-negative bacillus isolated from an adult stool culture is resistant to O/129, cannot grow in 6% NaCl broth, and is Voges-Proskauer positive. Which organism would you suspect?
 - a. *Aeromonas hydrophila*
 - b. *Aeromonas caviae*
 - c. *Plesiomonas shigelloides*
 - d. *Vibrio parahaemolyticus*
7. Darting motility is a characteristic of which organism?
 - a. *Aeromonas*
 - b. *Campylobacter*
 - c. *Vibrio cholerae*
 - d. *Arcobacter*
8. Which of the following tests is most helpful in differentiating *C. jejuni* from the other *Campylobacter* spp.?
 - a. Nitrate reduction
 - b. Urease activity
 - c. Hippurate hydrolysis
 - d. Susceptibility to nalidixic acid
9. When attempting to recover enteric *Campylobacter* spp., which specimen, media, and incubation conditions should be used?
10. Which nonculture methods are used to diagnose *Helicobacter pylori* infections?

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics of nonfermentative, gram-negative rods.
2. Compare the metabolic pathways used by nonfermentative organisms with those used by fermentative organisms.
3. Discuss the natural habitat of the nonfermentative, gram-negative bacilli.
4. Describe the types of infections that nonfermentative organisms cause and the patients who are at high risk for infections.
5. Characterize the most clinically significant nonfermentative gram-negative bacilli.
6. Discuss the incidence of infections caused by various nonfermenters in patients with cystic fibrosis.
7. Recognize the initial clues to nonfermentative organisms when isolated in clinical specimens.
8. Describe the typical biochemical reactions and key characteristic features of the most commonly encountered nonfermentative organisms.
9. Evaluate the typical antimicrobial susceptibility pattern of the most commonly encountered nonfermentative organisms.
10. Justify when a full identification and antimicrobial susceptibility test should be performed on a nonfermenting gram-negative bacillus.

KEY TERMS

Asaccharolytic

Eugonic oxidizer (EO)

Fermentative

Nonfermentative

Nonoxidizers

Oxidizers

Pseudomonas

Pyocyanin

Pyoverdine

Case in point

A 25-year-old female patient who received a bone marrow transplant as treatment for aplastic anemia presented with fever, chills, and malaise of about 2 days' duration. Two sets of blood cultures were drawn, 20 mL each. The patient was admitted, and because her fever persisted, another two sets of blood cultures were collected about 5 hours later. At this point, the patient was given a broad-spectrum antimicrobial agent, with the plan to give her antifungal agents if the fever persisted. About 12 hours after the first blood cultures had been drawn, both blood culture bottles in set one were positive for a gram-negative bacillus. Four hours later, the other two sets were also positive for a gram-negative bacillus. The next day, the clinician was informed that the gram-negative bacillus was an oxidase-positive, nonlactose fermenter. The laboratory

had recently instituted use of mass spectrometry for identification of gram-negative bacilli, and the final identification of the isolate was reported a few hours later, with an antimicrobial susceptibility test performed thereafter.

Issues to consider

After reading the patient's case history, consider:

- The risk factors in this patient for infection with a nonfermentative gram-negative bacillus
- The significance of the number of positive blood cultures and the time until the cultures were positive
- How you might rapidly identify this organism for better clinical care

Gram-negative bacilli can be divided into aerobic and obligate anaerobic bacilli. Aerobic gram-negative bacilli can be further divided into at least two large groups: those that ferment carbohydrates, called **fermentative** or *fermenters*, and those that do not ferment carbohydrates, called **nonfermentative** or *nonfermenters*. This chapter discusses miscellaneous nonfermentative organisms that are clinically significant because of the increasing numbers of patients who are immunocompromised. This group of patients often has multiple risk factors for infection with these normally uncommon pathogens. The groups of organisms discussed in this chapter include *Pseudomonas* spp., *Acinetobacter* spp., *Stenotrophomonas maltophilia* and *Burkholderia* spp., and other species that fail to metabolize carbohydrates.

General characteristics of nonfermenters

Nonfermenting gram-negative bacilli fail to acidify an oxidative-fermentative (OF) medium when it is overlaid with mineral oil or fail to acidify triple sugar iron agar (TSIA) butts. They prefer and grow much better in an aerobic environment; some do not grow in an anaerobic environment at all. Some group members oxidize carbohydrates to derive energy; they are referred to as **oxidizers**. Others do not break down carbohydrates at all; they are referred to as **nonoxidizers** or **asaccharolytic**. Additional characteristics can differentiate this group of nonfermenters from other gram-negative bacilli—motility, pigmentation, and their ability or lack of ability to grow on selective gram-negative media such as MacConkey (MAC) agar. Most nonfermentative, gram-negative bacilli are oxidase positive, a feature that differentiates them from the members of the order Enterobacterales (*Plesiomonas* sp. is the only oxidase-positive member of the order Enterobacterales). A variety of approaches to the phenotypic identification of aerobic gram-negative bacilli are available.

In general, nonfermentative, gram-negative bacilli or coccobacilli are ubiquitous and found in most environments, typically in soil and water, on plants and decaying vegetation, and in many foodstuffs. They prefer moist environments, and in hospitals, they can be isolated from nebulizers, dialysate fluids, saline, catheters, and other devices. Nonfermenters can withstand treatment with chlorhexidine and quaternary ammonium compounds. They are rarely, if ever, part of the normal host microbiota but can easily colonize hospitalized

patients, especially those who are immunocompromised. Many of the nonfermentative, gram-negative bacilli tend to be resistant to multiple classes of antimicrobial agents.

Clinical infections

Nonfermenters account for about 15% of all gram-negative bacilli isolated from clinical specimens. Although there are differences among the clinical diseases caused by each species, some common disease manifestations and risk factors can be found. Nonfermenters are responsible for a number of serious infections, including septicemia, meningitis, osteomyelitis, and wound infections, usually following surgery or trauma. Common risk factors for development of these infections are listed in [Box 21.1](#). Usually, the individual who contracts an infection with one of these organisms is hospitalized or has been discharged recently from the hospital.

Biochemical characteristics and identification

As noted, all nonfermenters fail to ferment carbohydrates and thus will not yield acidic reactions in the anaerobic portion of media, such as TSIA or Kligler iron agar (KIA). A fermenter (e.g., *Escherichia coli*) typically produces an acid (yellow) butt with an acid or alkaline (red) slant on TSIA or KIA within 18 hours of incubation on either of these media. A nonfermenter (an oxidizer or nonoxidizer) produces no change in the butt and slant or may produce an alkaline (red) slant. The principles of the TSIA reactions are explained in [Chapter 9](#). In addition to these types of organisms, some “true” fermenters are fastidious (e.g., *Pasturella multocida*) and do not easily acidify the butt or slant of a TSIA like other fermenters, but they do show reactions if more enriched media are used. Some characteristic clues can indicate the presence of a nonfermenter in the clinical laboratory:

- Oxidase-positive reaction, although reaction can be weak and variable

BOX 21.1 Risk factors for diseases caused by nonfermentative, gram-negative bacilli

Immunosuppression

Diabetes mellitus
Cancer
Steroids
Transplantation

Trauma

Gunshot, knife wounds, punctures
Surgery
Burns

Foreign body implantation

Catheters, urinary or bloodstream
Prosthetic devices—joints, valves
Corneal implants or contact lenses

Infused fluids

Dialysate
Saline irrigations

- Nonreactivity in 24 hours in commercial multitest kit systems used primarily for the identification of Enterobacterales
- No acid production in the slant or butt of TSIA or KIA
- Resistance to a variety of classes of antimicrobial agents, such as aminoglycosides, third-generation cephalosporins, penicillins, and fluoroquinolones

Many classification systems have been devised for grouping the nonfermenters. One system uses the reactions of three common tests: (1) growth on MAC agar, (2) oxidase reaction, and (3) the glucose OF test. The eight possible combinations of results are then used to group the nonfermenters, as shown in Fig. 21.1. Included in this figure are some isolates of nonfermentative, gram-negative bacilli not always considered with the more typical nonfermenters. Organisms such as *Brucella* spp. and *Bordetella* spp. are biochemically similar and are discussed in Chapter 18. For the identification of nonfermentative, gram-negative bacilli, conventional tube biochemical testing, multitest kit systems, automated systems, molecular biology methods involving deoxyribonucleic acid (DNA), or more recently, matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry can be used.

Four groups of nonfermenters make up most isolates routinely seen in clinical laboratories: *Pseudomonas aeruginosa*, *Acinetobacter* spp., *Burkholderia* spp., and *Stenotrophomonas maltophilia*. Any of the aforementioned systems perform adequately to identify these four groups. For the remainder of the nonfermenters, for which there remains great variability in the accuracy of identification depending on the system used, decisions must be made about whether a full identification is needed based on the clinical situation and relevance of the isolate. As a result of nucleic acid studies, the nonfermentative, gram-negative bacilli continually undergo taxonomic changes. Table 21.1 lists the present taxonomy of many nonfermenters. Box 21.2 summarizes characteristics common to some gram-negative nonfermenters.

The decision to identify many of the nonfermenters is based on the site from which they have been isolated; that is, whether they have been recovered from a normally sterile site in pure culture or from a nonsterile site in which three or four other bacterial species are also present. In the former case, it may be decided that definitive identification and susceptibility testing are required. In the nonsterile site, genus identification might be appropriate, which can be achieved through use of a few biochemical tests (e.g., oxidase, growth on MAC agar, glucose utilization, indole, and motility). Alternatively, identification as a nonfermenter, not *P. aeruginosa*, *Acinetobacter* spp., *Burkholderia* spp., or *S. maltophilia*, may be all that is needed, especially when cultures are mixed with many other bacterial species.

Definitive identification of every nonfermenter is time-consuming and can be costly. Fig. 21.2 illustrates typical biochemical and morphologic characteristics for many of the more common nonfermentative, gram-negative bacilli. If definitive identification is considered necessary for epidemiologic purposes or for academic reasons, such as for publication of an unusual case report involving the organism, clinical laboratory scientists should consider sending the isolate to a reference laboratory that is better equipped to achieve these identifications in a cost-effective manner. Today, many

reference laboratories use nucleic acid sequencing or mass spectrometry for identification rather than relying on biochemical or phenotypic identification for obtaining a definitive answer.

MALDI-TOF mass spectrometry identifies bacteria and fungi from colonies based on analysis of the unique spectra of their peptides when separated in a mass spectrometer; see Chapter 11. The identification can be made within minutes with a high level of accuracy and reproducibility compared with the gold standard of molecular sequencing. The mean time to identification of one isolate is 6 minutes, with a cost estimated at 20% to 30% lower than the conventional procedures that use phenotypic methods. In a study that compared biochemical methods with MALDI-TOF mass spectrometry using a 16S ribosomal ribonucleic acid (rRNA) gene sequencing method as the reference method for comparison, of 173 species-level identified strains from 187 clinical samples, 75% were identified correctly by API 20NE (bioMérieux, Durham, NC) strip, 83% by the VITEK 2 system (bioMérieux), and 89% by MALDI-TOF mass spectrometry. When the easily identified *S. maltophilia* strains were excluded, genus-level identification was 93% with MALDI-TOF mass spectrometry versus 76% with the API 20NE system and 81% with the VITEK 2 system.

For clinically significant isolates of *P. aeruginosa*, *S. maltophilia*, *Acinetobacter* spp., and *Burkholderia cepacia*, the Clinical and Laboratory Standards Institute (CLSI) recommends that a broth microdilution or Kirby-Bauer disk diffusion assay be performed. For other species, broth microdilution, not disk diffusion, is recommended if antimicrobial susceptibility testing is done at all.

Case check 21.1

When trying to determine the relevance of a particular isolate in a patient's culture, a physician often uses a combination of factors, including the risk factors that a patient may have for a variety of microbes. The relevance of isolation of nonfermentative bacilli from the sputum of an immunocompetent, healthy individual with a cough might differ from that in patients who are taking heavy doses of steroids because they have just received a lung transplant and they have cystic fibrosis (CF). Laboratories should consider contacting physicians when unusual isolates are cultured from clinical specimens to determine whether the workup should be more extensive in patients who have underlying risk factors. The patient in the Case in Point was a bone marrow transplant recipient and would fall into the at-risk group for development of infections with nonfermenters.

Clinically significant nonfermentative, gram-negative bacilli

The genus *Pseudomonas* accounts for the largest percentage of all nonfermenters isolated from clinical specimens. Characteristics common to most of the **pseudomonads** and several *Pseudomonas*-like organisms, include:

- Gram-negative bacillus or coccobacillus
- Strictly aerobic metabolism
- Motile, usually with polar flagellum or polar tuft of flagella

nonfermenters, consisting of 10 different genera. There are an additional 20 taxa of miscellaneous gram-negative bacilli included in the database. The ability to use one manual system to identify enterics and nonfermenters may be attractive to a smaller laboratory, even if the database

is limited, as it is in this system. The API 20NE is specifically for the identification of nonfermenters, and the API 20E is for enterics. The API 20NE performs well for most commonly isolated nonfermenters and is used in many clinical laboratories. The Remel RAPID NF Plus System

(Thermo Fisher Scientific, Waltham, MA) provides identification by analysis of preformed enzymes; 70 medically important nonfermenters, including members of the *B. cepacia* complex, can be identified in 4 hours. The Biolog microbial ID system (Biolog, Hayward, CA) is a microbial identification system that can be used manually or in fully automated format; the database contains over 2500 species of bacteria and yeasts, including most of the clinically relevant nonfermenters. The VITEK 2 and MicroScan systems (Beckman Coulter, Brea, CA) provide automated approaches to the identification of a variety of bacteria and yeasts that include many of the clinically relevant nonfermenters.

Today, MALDI-TOF mass spectrometry and nucleic acid sequencing are becoming more popular because of their ability to identify rapidly and accurately many more nonfermenters than can be done with phenotypic methods. The two instruments for performing MALDI-TOF mass spectrometry, the MALDI Biotyper (Bruker, Billerica, MA) and the VITEK MS, were compared for the identification of 200 nonfermenting bacilli isolated from CF patients at the University of Iowa Health Care. Both provided rapid and reliable (>89.5%) results with combined species, complex, and genus identification. More than 14 common and uncommon genera were included in this study. The two MALDI-TOF mass spectrometry instruments were compared in a study of 296 strains of many bacteria, including 49 nonfermenters. They provided very good identification, at least to the genus level, compared with gold standard sequencing identification. Identification of nonfermenters by 16S rRNA sequencing was compared with that accomplished with the API 20NE and VITEK 2 ID-GNB cards. About 92% of the isolates could be assigned to a species and 8% to a genus with sequencing compared with 54% to a species and 7% to a genus with the API 20NE, and 53% and 1% with VITEK 2 identification; 15% and 43%, respectively, were not found in the API 20NE and VITEK 2 databases.

***Pseudomonas* fluorescent group**

Pseudomonas aeruginosa

Pseudomonas aeruginosa is the most commonly isolated species of the genus in clinical specimens. It is found in moist environments, including tap water, pools, hot tubs, catheters, and humidifiers in hospitals, and in plants and soil. It is an uncommon part of the normal bacterial microbiota and is isolated from less than 12% of normal stool specimens. It can cause mild illness in healthy people and severe infections in people with weak immune systems. It may, however, account for 5% to 15% of all healthcare-associated infections, especially pneumonia and bacteremia. *P. aeruginosa* is the leading cause of healthcare-associated respiratory tract infections. A large variety of clinical diseases have been documented as being caused by *P. aeruginosa*, including bacteremia, often presenting with ecthyma gangrenosum; wound infections; pulmonary disease, especially among individuals with CF; healthcare-associated urinary tract infections (UTIs); endocarditis; bone infections; eye infections, including keratitis, ulcers, and endophthalmitis; infections following burns or trauma; and in rare cases, central nervous system infections, including meningitis.

P. aeruginosa accounts for up to 6% of all bacteremias and as many as 75% of healthcare-associated bacteremias and is the third most common cause of gram-negative bacillary bacteremia, after *E. coli* and *Klebsiella pneumoniae*. It is a common cause of lung infections in people with CF. Poor prognostic factors associated with *P. aeruginosa* bacteremia include septic shock, granulocytopenia, inappropriate antimicrobial therapy, and the presence of septic metastatic lesions. When *P. aeruginosa* is isolated from a sterile body site, such as blood, pleural fluid, joint fluids or tissues, or cerebrospinal fluid (CSF), it almost always constitutes a true infection.

Because *P. aeruginosa* can colonize mucosal surfaces, such as the oropharynx, patients in the intensive care unit (ICU) who are mechanically ventilated may quickly become colonized with *P. aeruginosa*. Positive cultures might not always indicate infection, although *P. aeruginosa* is a common cause of ventilator-associated pneumonia, especially in the immunocompromised or otherwise severely ill patient. Fig. 21.3 illustrates the Gram-stained smear of a bronchial specimen containing *P. aeruginosa*. Other less serious conditions associated with *P. aeruginosa* infection are otitis externa, particularly in swimmers or divers; necrotizing rash, referred to as *Jacuzzi* or *hot tub syndrome*, that develops in users of these recreational facilities; and infections of the nail beds in people with artificial nails.

Virulence factors

A variety of factors contribute to the pathogenicity of *P. aeruginosa*, such as endotoxin (lipopolysaccharide [LPS]), motility, pili, capsule, flagella, phospholipases, a type III secretion system, and several exotoxins (Table 21.2). The most important exotoxin is exotoxin A; this exotoxin functions similarly to diphtheria toxin by blocking protein synthesis. In lower respiratory tract infections of patients with CF, most *P. aeruginosa* strains produce mucoid colonies caused by the overproduction of alginate, a polysaccharide polymer (Fig. 21.4). The production of mucoid colonies in strains isolated from patients with CF can be a helpful identifying characteristic. *P. aeruginosa* is also inherently resistant to a number of antimicrobial agents. Despite the vast array of virulence factors, *P. aeruginosa* is still considered an opportunistic pathogen.

Fig. 21.3 Direct Gram-stained smear of bronchial specimen showing *Pseudomonas aeruginosa* (×1000).

Table 21.2 *Pseudomonas aeruginosa* virulence factors

Virulence factors	Function
Lipopolysaccharide	Antiphagocytic activity, cytotoxicity
Pili	Adhesion
Flagella	Motility, adhesion
Type III secretion system	Cytotoxic activity
Phospholipases	Cytotoxicity
Proteases	Cytotoxicity, proteolytic activity
Exotoxin A	Cytotoxicity
Capsule	Antiphagocytic activity
Deoxyribonuclease (DNase)	Breaks down DNA
Elastase	Cytotoxicity, proteolytic activity
Lecithinase	Cytotoxicity, proteolytic activity
Hemolysins	Cytotoxicity

LPS, Lipopolysaccharide.

Fig. 21.4 *Pseudomonas aeruginosa* on sheep blood agar. Left, Nonmucoid colonies. Right, Mucoid colonies. Note discoloration of media, especially on the left.

Case check 21.2

When a nonfermentative bacillus is isolated from a clinical specimen in the laboratory, it could represent a pathogen, a saprophytic bacterium that has become part of the microbiota of the patient, or contamination of the specimen that occurred during specimen collection, transport, or processing in the laboratory. The goal of the laboratory is to give accurate information to the clinical team so that they can best evaluate and interpret the results of the culture. More significance is often given to isolates of nonfermenters when they are isolated from normally sterile sites or isolated in large quantities from many different samples. In the Case in Point, *P. aeruginosa* was isolated from four blood cultures and grew relatively quickly, indicating that this is likely the pathogen responsible for the patient's symptoms.

Identifying characteristics

Members of the *Pseudomonas* fluorescent group, which includes *P. aeruginosa*, *P. fluorescens*, *P. putida*, *P. veronii*, *P. mosselii*, and *P. monteilii*, produce **pyoverdinin**, a yellow-green or yellow-brown pigment. Pyoverdinin is water soluble and fluoresces under short-wavelength ultraviolet light. Most strains of *P. aeruginosa* will also produce the blue, water-soluble

Fig. 21.5 *Pseudomonas aeruginosa* on MacConkey agar (A) and Mueller-Hinton agar (B). Note the blue-green pigment.

pigment **pyocyanin**. Pyocyanin combining with pyoverdinin produces the green color characteristic of *P. aeruginosa* colonies (Fig. 21.5). No other nonfermentative, gram-negative bacillus produces pyocyanin, so its presence can be used to specifically identify *P. aeruginosa*. If needed, pyocyanin typing can be used to epidemiologically link strains of *P. aeruginosa*. About 4% of clinical strains of *P. aeruginosa*, however, do not produce pyocyanin. Other water-soluble pigments, e.g., pyorubin (red) and pyomelanin (brown or black), are occasionally produced by strains of *P. aeruginosa*.

Most isolates of *P. aeruginosa* are β -hemolytic on sheep blood agar (SBA) and will produce flat, spreading colonies with a characteristic metallic sheen. Many strains also produce a fruity, grapelike odor caused by the presence of 2-aminoacetophenone. Other key characteristics of *P. aeruginosa* include denitrification of nitrates and nitrites, positive for arginine dihydrolase (ADH), growth at 42°C, citrate positivity, and acetamide utilization. Cetrimide agar is a selective and differential medium for the identification of *P. aeruginosa*. Cetrimide acts as a detergent and inhibits most bacteria; the medium also enhances the production of the two pigments produced by *P. aeruginosa*.

Treatment

P. aeruginosa is innately resistant to many antimicrobial agents, including penicillin, ampicillin, first- and second-generation cephalosporins, trimethoprim-sulfamethoxazole (SXT), chloramphenicol, and tetracyclines, along with other agents to which

most gram-negative bacilli are resistant. *P. aeruginosa* is usually susceptible to the aminoglycosides, semi-synthetic penicillins such as piperacillin and ticarcillin, third- and fourth-generation cephalosporins (ceftazidime and cefepime, respectively), carbapenems (except ertapenem), and the fluoroquinolones. Resistance to any of these agents may, however, develop while a patient is receiving therapy. The incidence of resistance is much higher in healthcare-associated strains of *P. aeruginosa*. Treatment of severe *P. aeruginosa* infections usually requires combination therapy, often with ceftazidime or cefepime, piperacillin, or a carbapenem (imipenem or meropenem) with an aminoglycoside (tobramycin or amikacin). Multidrug-resistant *P. aeruginosa* infections can be fatal in critically ill patients.

Pseudomonas fluorescens and *Pseudomonas putida*

Both *Pseudomonas fluorescens* and *P. putida* are of very low virulence, rarely causing clinical disease. They have been isolated from respiratory specimens, contaminated blood products, urine, cosmetics, hospital equipment, and fluids. *P. fluorescens* and *P. putida* have been documented, although rarely, as causes of UTIs, postsurgical abscesses, empyema, septic arthritis, and other wound infections. *P. putida* has been associated with catheter-related sepsis in patients with cancer; isolation of *P. fluorescens* from blood culture bottles in asymptomatic patients has been responsible for clusters of pseudobacteremia, probably related to contaminated catheters and catheter-related devices. Both species can grow at 4°C and have been linked to transfusion-associated septicemia.

P. fluorescens and *P. putida* produce pyoverdine, but neither produces pyocyanin or grows at 42°C, the key characteristics of *P. aeruginosa*. *P. fluorescens* and *P. putida* cannot reduce nitrate to nitrogen gas, but they can produce acid from xylose, characteristics that separate them from the other fluorescent group pseudomonads. Gelatin hydrolysis can be used to differentiate the two species from each other; *P. putida* is negative and *P. fluorescens* is positive. They are usually susceptible to the aminoglycosides, polymyxin, and piperacillin, but are resistant to carbenicillin and SXT.

Several more recently identified pseudomonads can be mistakenly identified as *P. fluorescens* by commercial phenotypic identification systems. These include *P. mosselii*, *P. veronii*, and *P. montelii*; sequence identification or MALDI-TOF mass spectrometry is needed for their specific identification. *P. mosselii* was first identified in 2002 during a study of strains of *P. fluorescens* and *P. putida*, when it was found that some isolates had low-level nucleic acid relatedness to other *Pseudomonas* strains. Colonies of *P. mosselii* are nonpigmented, nonhemolytic, and positive for oxidase, catalase, and ADH; optimal growth occurs at 30°C. A case of prosthetic valve endocarditis caused by *P. mosselii* was reported in the United Kingdom in 2009 that was successfully treated with piperacillin-tazobactam and ceftazidime. No surgery was needed to replace the valve, which was unusual compared with endocarditis caused by *P. aeruginosa*.

Case check 21.3

Laboratories often implement protocols when a susceptibility test would be performed on a nonfermenter. When *P. aeruginosa* is isolated from a sterile site such as a blood culture, most laboratories will provide this information as rapidly as possible so clinicians have the in vitro information they can use to develop a treatment regimen for their patient.

Pseudomonas nonfluorescent group

Pseudomonas stutzeri

Pseudomonas stutzeri, although a rare isolate and even rarer pathogen in the clinical laboratory, is usually easily recognizable because of its characteristic macroscopic appearance of wrinkled, leathery, adherent colonies that may produce a light-yellow or brown pigment (Fig. 21.6). Isolates are ADH negative and starch hydrolysis positive, the combination of which specifically distinguishes *P. stutzeri* from most other *Pseudomonas* spp. *P. stutzeri* is a soil denitrifier and can grow in an anaerobic environment in nitrate-containing media, producing nitrogen gas. This can differentiate the organism from other pseudomonads as well, although this is not a test commonly used in clinical laboratories.

In the immunocompromised host, *P. stutzeri* has been reported to be responsible for diseases that include septicemia, meningitis in people with human immunodeficiency virus infection, pneumonia (especially in patients with CF and those who are immunocompromised), endocarditis, postsurgical wound infections, septic arthritis, conjunctivitis, and UTIs. Isolates in vitro are usually susceptible to the aminoglycosides, SXT, ampicillin polymyxin, tetracyclines, fluoroquinolones, and third-generation cephalosporins (e.g., ceftazidime) but resistant to chloramphenicol and the first- and second-generation cephalosporins. Because of the adherent nature of colonies of *P. stutzeri*, identification of the organism and in vitro susceptibility testing can be unreliable.

Fig. 21.6 *Pseudomonas stutzeri* on sheep blood agar. Note the wrinkled appearance of the colonies.

Pseudomonas mendocina

Pseudomonas mendocina can be found in soil and water but is rarely isolated from human specimens; when it is, it is often considered a contaminant. There are rare cases of endocarditis described in the literature. *P. mendocina* produces nonwrinkled, flat colonies that may appear with a yellowish-brown pigment. Pigmentation seems to be a variable trait, but many exhibit a smooth buttery appearance. It is oxidase and ADH positive, like *P. aeruginosa*, but does not produce pyoverdine and is acetamide negative. *P. mendocina* is motile by means of a single polar flagellum, it oxidizes glucose and xylose, and is nonproteolytic and does not hydrolyze starch.

Pseudomonas pseudoalcaligenes and *Pseudomonas alcaligenes*

Pseudomonas pseudoalcaligenes and *Pseudomonas alcaligenes* are often considered contaminants when isolated from clinical specimens. They are oxidase positive and biochemically negative in many tests for which other *Pseudomonas* spp. test positive. They grow on MAC agar and are variable in the reduction of nitrates to nitrites or nitrogen gas. They are motile by means of a polar flagellum. *P. pseudoalcaligenes* is ADH positive and will weakly ferment fructose, two characteristics that differentiate it from *P. alcaligenes*. Commercial systems usually cannot discriminate the two species, and other methods of identification such as MALDI-TOF mass spectrometry or DNA sequencing are needed for definitive species differentiation. Few reports are available about the in vitro susceptibility of these species.

Pseudomonas luteola and *Pseudomonas oryzae*

The natural habitat of *Pseudomonas luteola* and *Pseudomonas oryzae* is unknown, although members of both genera have been isolated from soil and water. *P. oryzae* has been found in Japanese rice paddies and has been isolated from hospital drains and respiratory therapy equipment. These two pseudomonads are rarely isolated from humans but have been isolated from wounds, abscesses, blood cultures, peritoneal and chronic ambulatory peritoneal dialysis (CAPD) fluids, and other sources. They have also been implicated in cases of peritonitis and possibly meningitis, although often in association with each other or with other bacteria. *P. luteola* has been recovered as the only isolate from a case of prosthetic valve endocarditis and subdiaphragmatic abscess and from multiple brain abscesses in a child. *P. oryzae* has been isolated from the eye of one patient with postoperative endophthalmitis. There appears to be a higher risk for infection by these organisms in the presence of foreign materials (e.g., catheters), corticosteroid use, and immunocompromised states. A 9-year-old male patient was bitten by an octopus while swimming in the ocean and developed an infection with *P. oryzae*. The ulcerative wound healed once the lesion had been incised.

Both of these pseudomonads are gram-negative, nonfermentative, oxidase-negative bacilli. They are catalase positive and motile, oxidize glucose, grow on MAC agar, and often produce an intracellular nondiffusible yellow pigment. Both species typically produce wrinkled or rough colonies at 48 hours (Fig. 21.7). *P. luteola* can be differentiated from *P. oryzae* by positive *o*-nitrophenyl- β -D-galactopyranoside (ONPG) and esculin hydrolysis tests. *P. luteola* and *P. oryzae* are susceptible to aminoglycosides, third-generation

Fig. 21.7 *Pseudomonas oryzae* wrinkled yellow colonies on sheep blood agar plate at 48 hours.

cephalosporins, ureidopenicillins, and quinolones. *P. oryzae* isolates are resistant to first- and second-generation cephalosporins but are usually susceptible to penicillin. *P. luteola* is usually sensitive to all β -lactams.

Acinetobacter

The genus *Acinetobacter*, now a member of the family Moraxellaceae, consists of 25 DNA homology groups or genomospecies. Only about 12 species have been named; the two species most commonly seen in clinical specimens are *A. baumannii*, glucose-oxidizing, nonhemolytic, and *A. lwoffii*, glucose-non-oxidizer, nonhemolytic. Most hemolytic strains of *Acinetobacter* are *A. haemolyticus*. *Acinetobacter* spp. are ubiquitous in the environment in soil, water, and foodstuffs. In the hospital environment, they have been associated with ventilators, humidifiers, catheters, and other devices. About 25% of adults carry the organisms on their skin, and about 7% carry the organisms in their pharynx. If not already harboring *Acinetobacter* spp., hospitalized patients become easily colonized. As many as 45% of patients with a tracheostomy may be colonized. While severe infections by *A. baumannii* have been described, colonization is probably more common, and it is difficult to distinguish between the two conditions.

In the past, when *Acinetobacter* spp. were isolated from nonsterile sites such as urine and many different types of respiratory specimens, they were usually considered insignificant colonizers or contaminants. However, with increased isolates of *Acinetobacter* that demonstrate resistance to most antimicrobial agents, including the carbapenems, their clinical significance when isolated from respiratory or urine specimens in a hospitalized immunocompromised patient cannot be dismissed routinely. Ventilator-associated pneumonia and sepsis caused by *A. baumannii* have a high mortality rate.

Clinical infections

Acinetobacter spp. are opportunists, accounting for 1% to 3% of all healthcare-associated infections. They are second only to *P. aeruginosa* in frequency of isolation of all nonfermenters in the clinical microbiology laboratory. *Acinetobacter* infections primarily affect patients with weakened immune systems and coexisting diseases. These infections usually occur

Fig. 21.8 *Acinetobacter baumannii* on Gram-stained smear. Note the coccoid nature of the cells as well as the pleomorphic forms ($\times 1000$).

in areas with a high fluid content such as the urinary tract and respiratory tract, and in peritoneal fluids. Diseases with which they have been associated (in particular *A. baumannii*) include UTIs; pneumonia, tracheobronchitis, or both; endocarditis, with up to a 22% mortality; septicemia; meningitis, often as a complication of intrathecal chemotherapy for cancer; and cellulitis, usually as a result of contaminated indwelling catheters, trauma, burns, or introduction of a foreign body. There are reports of eye infections caused by *A. baumannii*, including endophthalmitis, conjunctivitis, and corneal ulcerations.

Although *A. baumannii* has been rarely associated with skin and soft tissue infections in the past, it is now emerging as an important opportunistic multidrug-resistant (MDR) pathogen of skin and soft tissue infections. In 2004, the Centers for Disease Control and Prevention (CDC) reported an increased number of MDR *A. baumannii* bloodstream infections in U.S. military personnel returning from service in Iraq and Afghanistan who had suffered traumatic injuries. A fatal case of MDR *A. baumannii* soft tissue infection was reported in 2014 involving a 41-year-old morbidly obese man with history of alcoholic liver disease. *A. lwoffii* is much less virulent, and when isolated, it usually indicates contamination or colonization rather than infection.

Identifying characteristics

All *Acinetobacter* spp. are strictly aerobic, and they appear as gram-negative coccobacilli or even gram-negative cocci on Gram stain (Fig. 21.8). *Acinetobacter* organisms can resist decolonization and retain the crystal violet stain, leading to misidentification. They can appear as gram-positive cocci in smears made from blood culture bottles. *Acinetobacter* spp. are oxidase negative, catalase positive, and nonmotile. They have few growth requirements and thus are capable of growing on most laboratory media, including MAC agar. The purplish hue (from aerobic acidification of lactose) produced by some species on this medium may resemble that of a lactose-fermenting bacterium (Fig. 21.9). *A. baumannii* is saccharolytic, and *A. lwoffii* is asaccharolytic.

Fig. 21.9 *Acinetobacter baumannii* on MacConkey agar. This organism is saccharolytic, which may cause it to resemble a lactose-fermenting organism.

Isolates of *A. baumannii* are often resistant to many antimicrobials, including penicillins, first- and second-generation cephalosporins, and fluoroquinolones. *A. baumannii* demonstrates variable susceptibility to the aminoglycosides and β -lactam plus β -lactamase inhibitor combinations (e.g., ampicillin-sulbactam, piperacillin-tazobactam). Many strains exhibit resistance to carbapenems; carbapenemases have been reported throughout the United States. These isolates have been referred to as CRAB, or carbapenem-resistant *A. baumannii*. CRAB isolates are usually only susceptible to colistin and tigecycline. Isolation of patients in mobile isolation chamber units is often enforced when CRAB is isolated. *A. lwoffii* is susceptible to almost all antimicrobials, another characteristic distinguishing it from *A. baumannii*.

Stenotrophomonas maltophilia

Stenotrophomonas maltophilia is the third most common nonfermentative, gram-negative bacillus isolated in the clinical laboratory. Before 1983, it was a member of the genus *Pseudomonas*; it was later reclassified as a member of the plant pathogen genus *Xanthomonas*. After DNA homology and sequencing analysis, it was classified as a member of the genus *Stenotrophomonas*, where it remains today. Isolates are ubiquitous in the environment, being found in water, sewage, and plant materials; they are very common in the hospital environment, where they can be found contaminating blood-drawing equipment, disinfectants, transducers, and other equipment.

Clinical infections

When *S. maltophilia* is isolated from clinical specimens, it is initially regarded as a saprophyte or colonizer. Although not considered part of the normal human microbiota, *S. maltophilia* can quickly colonize the respiratory tract of hospitalized patients, in particular those exposed to antimicrobial agents to which *S. maltophilia* may be inherently resistant. These antimicrobials include cephalosporins, penicillins,

carbapenems, and aminoglycosides. There have been more reports of disease attributed to this organism, including endocarditis, especially in a setting of prior intravenous drug abuse or heart surgery; wound infections, including cellulitis and ecthyma gangrenosum; bacteremia; and, rarely, meningitis and UTIs. With rare exceptions, infections have occurred in a health care setting. *S. maltophilia* is rarely associated with lower respiratory tract infections, although it has been isolated from 6.4% to 10.2% of patients with CF.

In a retrospective study of 158 patients who had infections caused by nonfermenters other than *P. aeruginosa* and *A. baumannii*, 39% were caused by *S. maltophilia*, followed by *Achromobacter* spp. and non-*baumannii* *Acinetobacter* species. The most important risk factors in affected individuals were immunosuppression, hospitalization, especially in an ICU, and the presence of a central venous catheter. The mortality in patients with *S. maltophilia* infections was associated with inappropriate antimicrobial treatment because many were initially given a carbapenem. The association with inappropriate therapy and increased mortality was not seen with other non-fermenter infections.

Identifying characteristics

S. maltophilia is an oxidase-negative, nonfermentative, gram-negative bacillus. Colonies may appear bluish on MAC agar. In addition, it is positive for catalase, DNase, esculin and gelatin hydrolysis, and lysine decarboxylase. *S. maltophilia* is usually susceptible to SXT, so this is the drug of choice for most infections. Other agents to which it may demonstrate in vitro susceptibility include ticarcillin-clavulanate, the fluoroquinolone levofloxacin, and tetracyclines, including tigecycline. The CLSI recommends broth microdilution testing for *S. maltophilia*; in addition, an Epsilonometer test (Etest) or agar dilution can be performed.

Burkholderia

Burkholderia cepacia complex

Burkholderia cepacia complex contains at least 20 distinct genomic species (genomovars), and all species within the complex have been isolated from humans. *B. cepacia* complex contains plant pathogens that have arisen as opportunistic organisms, usually associated with pneumonia in patients with CF or chronic granulomatous disease (CGD). In addition, members of this complex have been reported to cause endocarditis (specifically in intravenous drug abusers), pneumonitis, UTIs, osteomyelitis, dermatitis, and other wound infections resulting from the use of contaminated water. They have been isolated from fluids used in the hospital (intravenous fluids and irrigation fluids), anesthetics, nebulizers, detergents, and disinfectants. Research supports the association of *B. cepacia* complex and increased severity of disease and death in patients with CF and CGD.

In the United States, the members of *B. cepacia* complex that account for most isolates recovered from clinical specimens are *B. cenocepacia* and *B. multivorans*. Other important isolates are *B. vietnamiensis*, *B. cepacia*, and *B. contaminans*. About 3% of the CF population is infected with *B. cepacia* complex, but rates up to 30% in some adult CF patients have been reported. Outside these populations, morbidity and mortality rates remain low, and consideration must be given

Fig. 21.10 *Burkholderia cepacia* on selective media. Left, Colonies of *B. cepacia* on oxidative-fermentative base, polymyxin B, bacitracin, and lactose (OFBBL) agar are yellow. Right, Colonies of *B. cepacia* on *Pseudomonas cepacia* agar are white, surrounded by a pink-red pigment.

to the possibility of contamination rather than infection when it is isolated in a non-CF or non-CGD individual.

The organisms grow well on most laboratory media but may lose viability on SBA in 3 to 4 days without transfers. Most members of the *B. cepacia* complex grow on MAC agar. Selective media containing antimicrobials to reduce the growth of *P. aeruginosa*, as well as other gram-negative bacilli, are available to increase the recovery of *B. cepacia* (Fig. 21.10). These include *Pseudomonas cepacia* oxidative-fermentative base, polymyxin B, bacitracin, and lactose (OFBL) agar, and *Burkholderia cepacia*-selective agar (BCSA). Studies suggest that BCSA is most effective in reducing overgrowth while maintaining good recovery of *B. cepacia*. Colonies of *B. cepacia* are nonwrinkled, and this trait may be used to differentiate isolates from *P. stutzeri*, which also produces a yellow pigment. *B. cepacia* does not fluoresce like *P. aeruginosa*, but it can produce a nonfluorescing yellow or green pigment that may diffuse into the media.

B. cepacia complex often produces a weak, slow, positive oxidase reaction. Almost all strains oxidize glucose, and many will oxidize maltose, lactose, and mannitol. Most strains are lysine decarboxylase positive, ONPG positive, ornithine decarboxylase negative, and fail to reduce nitrate to nitrite. Isolates are motile by means of polar tufts of flagella. Species identification among the genomovars of *B. cepacia* complex is difficult, and when a commercial system is used, confirmation should follow with supplemental biochemical, MALDI-TOF mass spectrometry, or molecular methods.

B. cepacia complex isolates are intrinsically resistant to aminoglycosides and polymyxins; in addition, many strains are resistant to several β -lactam antibiotics. Isolates may, however, be susceptible to chloramphenicol, ceftazidime, piperacillin, minocycline, some fluoroquinolones, and SXT. Susceptibility to the carbapenems is variable. Resistance can develop rapidly while a patient is being treated.

Burkholderia mallei

Burkholderia mallei causes glanders, a respiratory tract zoonosis primarily affecting livestock such as horses, mules, and donkeys. It is rare in humans but can produce severe local suppurative or acute pulmonary infections. The organism is considered by government agencies to be a potential bioterrorism agent; see Chapter 30. The only case of glanders in the United States in the past 50 years was caused by a laboratory accident in 2000; however, it is still endemic in parts of Africa, Asia, the Middle East, and Central and South America. India had remained free from glanders in livestock for more than 10 years when outbreaks occurred in 2006 to 2007 in which 164 horses were found positive in 8 Indian states. *B. mallei* is host adapted and does not grow in the environment.

B. mallei is a nonmotile, gram-negative coccobacillus that produces nonpigmented colonies in 2 days. Growth on MAC agar and oxidase production is variable; glucose is oxidized, nitrates are reduced to nitrites, and isolates are ADH positive. Like *B. cepacia* complex, isolates are resistant to polymyxins. If susceptibility tests are performed—and because of virulence should be performed only in approved laboratories—the CLSI recommends that a broth microdilution with *Brucella* broth and incubation at 35°C in ambient air for 16 to 20 hours be the method used. The drugs to consider testing for both *B. mallei* and *B. pseudomallei* should be ceftazidime, imipenem, doxycycline, and tetracycline.

Burkholderia pseudomallei

Burkholderia pseudomallei causes melioidosis, an aggressive, granulomatous, pulmonary disease caused by ingestion, inhalation, or inoculation of the organisms, with metastatic abscess formation in lungs and other viscera. Overwhelming septicemia can occur. Local infections, including orbital cellulitis, dacryocystitis, and draining abscesses, are sometimes seen, with pneumonia being the most common presentation. The incubation period may be prolonged, with reactivation occurring long after exposure.

The organisms are found in water and muddy soils in Southeast Asia (including Vietnam and Thailand), northern Australia, and Mexico. Those who have traveled to endemic areas are at risk for infection with *B. pseudomallei*. However, in 2021, four non-travel-related cases of *B. pseudomallei* infections were reported in several states including Georgia, Kansas, Texas, and Minnesota. None of the patients' families reported a history of traveling outside of the continental United States. The CDC investigation identified *B. pseudomallei* in an aromatherapy spray that was found in the home of the Georgia patient, and the genetic fingerprint of the bacteria in the bottle matched those of the bacteria identified in the four patients. Because the symptoms of melioidosis are varied and nonspecific, which may include pneumonia, abscess formation, and/or blood infections, the disease can initially be mistaken for other diseases such as tuberculosis, and proper treatment may be delayed.

This organism should be considered, especially when a nonfermentative wrinkled colony is isolated (Fig. 21.11) that demonstrates bipolar staining on Gram-stained smears. *P. stutzeri*, which can also appear as wrinkled colonies, does not use lactose, in contrast with *B. pseudomallei*. A selective medium, Ashdown medium, is supplemented with colistin; colonies on this agar are deep pink because of the absorption of neutral red in the medium. Colonies will also exhibit an earthy odor; however, work should be done in a biological

Fig. 21.11 *Burkholderia pseudomallei* on sheep blood agar.

safety cabinet when *B. pseudomallei* is suspected. As with all organisms, sniffing of plates is discouraged.

Identification of *B. pseudomallei* is generally accurate in many of the commercial manual nonfermenter systems. Identification involving automated algorithms (e.g., MALDI-TOF mass spectrometry, 16s, VITEK 2) has been shown unsuccessful and may misidentify *B. pseudomallei* as another bacterium. Use of multiplex polymerase chain reaction (PCR) assays for the identification of many of the *Burkholderia* spp., including *B. cepacia* complex and *B. pseudomallei*, has been shown to be of tremendous value to clinical microbiologists for rapid and accurate laboratory diagnosis. *B. pseudomallei* is considered a potential bioterrorism agent. If *B. pseudomallei* is isolated from someone who has never traveled to an endemic area, its occurrence should be reported to local or state public health departments.

Although isolates may be susceptible in vitro to many antimicrobial agents, including SXT, chloramphenicol, tetracycline, semi-synthetic penicillins, and ceftazidime, the clinical response to therapy is usually slow, and relapses are common. SXT and the fluoroquinolones seem to work well clinically. As with many of the nonfermenters, the CLSI does not recommend disk diffusion susceptibility testing.

Burkholderia gladioli

The plant pathogen, *Burkholderia gladioli* resembles *B. cepacia* complex. Isolates have been found in patients with CF and CGD. *B. gladioli* has been recovered from the blood and tissue of immunocompromised patients, particularly CF patients who have had a lung transplant. The 1-year (all-cause) mortality has been reported to be as high as 23%. A yellow pigment may be produced, especially after 48 to 72 hours of incubation. These organisms are motile by means of one or two polar flagella and are catalase and urease positive. *B. gladioli* grows on MAC agar, oxidizes glucose, is mannitol positive and decarboxylase negative, and is negative for oxidase, although some strains are weakly positive. Specific species identification of *B. gladioli* is difficult without the use of molecular tools for confirmation because isolates can be misidentified in commercial phenotypic systems as a member of the *B. cepacia*

complex. *B. gladioli* isolates are more susceptible to antimicrobials than *B. cepacia* and will be susceptible to aminoglycosides, carbapenems, ciprofloxacin, and SXT, but resistant to aztreonam and the cephalosporins, and 100% resistant to polymyxin B.

Moraxella*, *Oligella*, and *Psychrobacter

Moraxella and *Oligella*, along with *Acinetobacter* and *Psychrobacter*, are members of the family Moraxellaceae. *Moraxella* spp. are nonmotile, strongly oxidase-positive, gram-negative coccobacillary to bacillary organisms. They are, in general, biochemically inert with regard to carbohydrate oxidation (asaccharolytic). They are strictly aerobic and usually susceptible to penicillin, an unusual characteristic for a nonfermenter. These isolates are opportunists that reside on the mucous membranes of humans and lower animals and can be isolated from the respiratory tract, urinary tract, and eyes. However, they rarely cause disease in humans, with the exception of *M. catarrhalis*. Members of the genus *Moraxella* that are commonly encountered include *M. catarrhalis*, *M. nonliquefaciens*, *M. lacunata*, *M. osloensis*, *M. lincolnii*, and *M. atlantae*. *M. phenylpyruvica* has been reclassified as *Psychrobacter phenylpyruvicus*.

M. catarrhalis is the most frequent isolate in the genus *Moraxella* from clinical specimens, especially from respiratory and ear specimens. This species resembles the *Neisseria* by exhibiting gram-negative coccoid morphology, and at one time was named *Neisseria catarrhalis* and also *Branhamella catarrhalis*. *M. catarrhalis* is discussed in [Chapter 17](#) because of its phenotypic similarity to the *Neisseria*.

M. nonliquefaciens is the second most commonly isolated member of the genus. It often resides as normal biota in the respiratory tract and rarely causes disease in humans. Rare cases of bacteremia, keratitis, endocarditis, and endophthalmitis caused by *M. nonliquefaciens* have been reported. The organism does not usually grow on MAC agar. *M. osloensis* is similar morphologically and biochemically to *M. nonliquefaciens*; it is found as normal biota in the genitourinary tract. *M. lacunata* is a common conjunctival isolate.

Members of the genus *Oligella* include *O. urethralis* and *O. ureolytica*. *Oligella* are small, paired, gram-negative bacilli or coccoid organisms, usually isolated from the urinary tract. These organisms usually do not grow on MAC agar, are non-oxidative, phenylalanine deaminase (PDA) positive, oxidase positive, and nitrate and nitrite positive with gas formation. Most strains of *O. ureolytica* are motile by means of peritrichous flagella—hence, the relationship to *Alcaligenes* and *Taylorella*. The PDA positivity helps differentiate them from *Alcaligenes* spp. *O. urethralis* is nonmotile. *O. ureolytica* was reported to cause bacteremia in a patient with acquired immunodeficiency syndrome and in an 18-month-old child with pneumonia. *O. urethralis* is a commensal of the genitourinary tract, but it has been rarely associated with urosepsis, and there was a report of a case of infectious arthritis that was mistaken for gonococcal arthritis. *Oligella* spp. are usually susceptible to most antimicrobials, including penicillin, although resistance has been detected in some strains, and susceptibility testing should be performed if this is deemed clinically significant.

The genus *Psychrobacter* contains about 50 species. They have been isolated from fish, processed meat, and poultry. *Psychrobacter sanguinis* and *Psychrobacter phenylpyruvicus* are the species most frequently recovered from humans. Clinically, they have been isolated from the eye of a newborn, who had acquired the infection nosocomially via a

water source, and from the blood and CSF of a 2-day-old newborn. They have been isolated from urine, blood, CSF, and the genitourinary tract.

Psychrobacter spp. are nonmotile, oxidase-positive, oxidative diplococci. Isolates grow well at 5° to 25°C but rarely at 35°C. They are nitrate positive and can grow on modified Thayer-Martin medium. An odor of roses (resembling phenylethyl alcohol) has been reported. Tween 80 added to the medium stimulates growth. Isolates resemble *Moraxella* but are usually not penicillin susceptible. They are susceptible to most other antimicrobial agents.

Less commonly encountered nonfermentative, gram-negative bacilli

Alcaligenes* and *Achromobacter

The family Alcaligenaceae includes the clinically relevant genera *Alcaligenes*, *Achromobacter*, *Bordetella*, *Advenella*, and *Kertesia*. Isolates of both *Alcaligenes* and *Achromobacter* are found in water (e.g., swimming pools, tap water, dialysis fluids) and are resistant to disinfectants, such as chlorhexidine and quaternary ammonium compounds. They are isolated in specimens from hospitalized patients such as urine, feces, sputum, and wound specimens. The asaccharolytic members of this group are less likely isolated from clinical specimens than the saccharolytic species. Among the asaccharolytic members, *A. faecalis* is the species usually seen in clinical specimens, and it has been isolated from the blood of patients with and without septicemia. It has also been linked to eye infections, pancreatic abscesses, and other infections.

Achromobacter spp. can be divided into asaccharolytic species (*Achromobacter piechaudii* and *Achromobacter denitrificans*) and saccharolytic species (*Achromobacter xylosoxidans* and the unnamed *Achromobacter* groups B, E, and F). *A. piechaudii* has been isolated from the ear of a diabetic patient. Gram-stained smears of the exudate were positive for gram-negative bacilli and gram-positive cocci. Both coagulase-negative staphylococci and *A. piechaudii* were repeatedly isolated. The patient recovered once the diabetes was stabilized.

A. xylosoxidans is the most commonly isolated member of the genus *Achromobacter*. A 10-year analysis of 54 cases of *A. xylosoxidans* bacteremia demonstrated that it is a cause of nosocomial infection associated with the use of intravenous catheters; patients who are of advanced age and experiencing neutropenia are most susceptible to serious and sometime fatal (15%) illness. In addition, it has been associated with cases of otitis media, meningitis, pneumonia, surgical wound infections, UTIs, peritonitis, and bacteremia. It is a frequent colonizer in patients with CF. The genus *Advenella* contains one species, *A. incenata*, described in 2005. Although their significance is unclear, isolates have been recovered from sputum, wounds, and blood.

Alcaligenes faecalis and *Achromobacter* spp. possess peritrichous flagella ([Fig. 21.12](#)) and are obligately aerobic gram-negative bacilli. These organisms usually grow well on most laboratory media, including MAC agar. On SBA, most species are nonpigmented ([Fig. 21.13](#)). Some strains may produce a fruity odor and cause a green discoloration on SBA. In OF media, most isolates are nonoxidative and produce a deep blue color at the top, except for *A. xylosoxidans*, which produces an acid reaction with glucose and xylose (hence the

Fig. 21.12 Flagella stains of gram-negative bacilli. **A**, Peritrichous flagella (e.g., *Alcaligenes faecalis* and *Achromobacter* spp.) ($\times 1000$). **B**, Polar, monotrichous (e.g., *Pseudomonas aeruginosa*) ($\times 1000$). **C**, Polar, multitrichous (e.g., *Comamonas* spp.) ($\times 1000$).

Fig. 21.13 *Achromobacter xylosoxidans* on sheep blood agar.

name). All species reduce nitrates to nitrites; *A. xylosoxidans* and *A. faecalis* can further reduce nitrites to nitrogen gas.

The asaccharolytic members of the group, *A. faecalis* and *A. piechaudii*, are usually susceptible to SXT, piperacillin, ticarcillin, ceftazidime, and quinolones (although variability occurs). Resistance to aztreonam and the aminoglycosides is common. Some strains of *A. piechaudii* may be susceptible to amoxicillin. *A. xylosoxidans* is usually resistant to aminoglycosides, ampicillin, first- and second-generation cephalosporins, chloramphenicol, and fluoroquinolones, but is usually susceptible to piperacillin, third-generation cephalosporins, carbapenems, and SXT. Resistance to all of these antimicrobial agents has been increasing, however, especially in immunocompromised patients in whom *A. xylosoxidans* is isolated.

Brevundimonas

Brevundimonas spp. are infrequent isolates in clinical microbiology laboratories. *Brevundimonas diminuta* has been found in blood, CSF, urine, and wounds; it is often considered a contaminant. A clinical isolate in an immunocompromised patient, however, was recently considered to be a pathogen. The isolate carried a VIM-2-metallo- β -lactamase, contributing to its multidrug resistance. *B. diminuta* isolates are motile and possess a single polar flagellum, oxidize glucose, and are oxidase positive. Most strains grow on MAC agar. In vitro, the organism demonstrates resistance to ampicillin, cefoxitin, and nalidixic acid; intrinsic resistance to fluoroquinolones has been detected.

B. vesicularis has been reported as a cause of meningitis, infective endocarditis, and infections in a CAPD patient; it was also isolated, with unknown significance, from urine and eye specimens. In 2012, there was a report of eight neonates in one neonatal ICU who had *B. vesicularis* septicemia, and three of the eight neonates also had meningitis caused by the organism. In addition, other cases of bacteremia have been described. Laboratory scientists should realize that *Brevundimonas* can be a significant pathogen. Like *B. diminuta*, *B. vesicularis* is a slender rod, with polar flagella. Only about 25% of *B. vesicularis* strains will grow on MAC agar. Most strains of *B. vesicularis* produce an orange intracellular pigment. *B. vesicularis* is also oxidase positive and oxidizes glucose and maltose. Esculin hydrolysis is the best test to differentiate the two species; approximately 88% of *B. vesicularis* isolates are positive, whereas *B. diminuta* isolates are rarely positive. *B. vesicularis* has been described as susceptible to fluoroquinolones and

piperacillin-tazobactam, but resistant to carbapenems, aztreonam, and the cephalosporins.

CDC groups EO-3, EO-4, and *Paracoccus*

The taxonomy of Centers for Disease Control and Prevention (CDC) groups EO-2, EO-3, and EO-4 is unclear; EO refers to **eugonic oxidizer**. EO-2 has been named *Paracoccus yeei*. Isolates of *P. yeei* have been recovered from blood cultures and wound infections and a cutaneous bulla in a 67-year-old male patient. It was also found in at least one case of uveitis, for which it was considered the potential pathogen. It has been seen in infections following keratoplasty, myocarditis in a heart transplant patient, and infection associated with CAPD. EO-3 has been reported in a case of CAPD infection. Isolates of EO-3 and EO-4 have been obtained from urine, eye discharge, blood, pleural fluid, and CSF and from lung, throat, and genitourinary tract specimens, in which their clinical significance remains unclear.

Isolates of *P. yeei*, EO-3, and EO-4 are oxidase-positive, nonmotile, saccharolytic coccobacilli that grow weakly, if at all, on MAC agar. They all oxidize glucose and xylose, but differ in oxidation of lactose and mannitol. EO-3 and many EO-4 isolates have a yellow nondiffusible pigment. *P. yeei* is further characterized by the production of characteristic coccoid or O-shaped cells on Gram stain, the latter of which results from the presence of vacuolated or peripherally stained cells. Susceptibility to antimicrobial agents is not well known.

Chromobacterium

Chromobacterium violaceum is the only clinically relevant species in the genus. The reservoirs are soil and water; isolates are more commonly found in tropical and subtropical climates, particularly in Southeast Asia and India. *C. violaceum* is an opportunist, attacking immunocompromised patients with neutrophil deficits, including CGD, usually as a result of contamination of wounds with water or soil. It has been isolated from cases of osteomyelitis, abscesses, and septicemia as well as from urine and gastrointestinal infections. A skin lesion is the typical portal of entry.

C. violaceum is a fermentative, gram-negative bacillus that might be oxidase positive, so it may be mistaken initially as a nonfermenter in the laboratory. It is motile with polar flagella and, as its name implies, produces a violet pigment about 91% of the time. The pigment is violacein, an ethanol-soluble, water-insoluble pigment. The presence of the pigment can hamper proper oxidase reactions. Isolates are usually motile, catalase positive, and indole negative (nonpigmented strains may be indole positive). Isolates ferment glucose and, variably, sucrose; they grow on MAC agar and most enteric media, reduce nitrate, and grow at 42°C. On Gram stain, the organisms may appear as curved bacilli that resemble vibrios, which are also oxidase positive. Nonpigmented strains have been confused with *Aeromonas* spp.

In 2011, 106 patients with *C. violaceum* infections were reported in a clinical review article. Fever, sepsis, skin lesions, and abdominal pain were the most common presenting symptoms, and the liver was the most common site of localized abscesses. The most important risk factors for death in *C. violaceum* bacteremia were young age, presence of localized abscess, shorter clinical course, and inappropriate

antimicrobial treatment. Relapse and reinfections also seemed to occur with these infections. Most isolates of *C. violaceum* are sensitive to fluoroquinolones, tetracyclines, carbapenems, gentamicin, and SXT but resistant to β -lactam antibiotics.

Comamonas and *Delftia*

Comamonas spp. and *Delftia* spp. are straight to slightly curved rods, produce alkalinity in OF media, are catalase and oxidase positive, are usually motile by multitrichous polar flagella, and reduce nitrate to nitrite. Ubiquitous in soil and water, they are rarely isolated from clinical specimens but have been found in hospital equipment and fluids. It is phenotypically difficult to distinguish among the *Comamonas* spp.; therefore isolates are often reported as *Comamonas* spp.

Isolates of *C. testosteroni* and *C. terrigena* have been reported to cause nosocomial bacteremia. In 2011 a review of the literature found 28 cases of *C. testosteroni* infection and a total of seven bacteremias. One patient receiving hemodialysis experienced *C. testosteroni* bacteremia accompanied by endocarditis and signs of peripheral embolism. The case had a fatal outcome.

Delftia acidovorans has been associated with keratitis in soft contact lens wearers and nosocomial infections including bacteremia and endocarditis. *D. acidovorans* can oxidize fructose and mannitol like the *Comamonas* spp. Some strains produce a fluorescent pigment. Isolates of *D. acidovorans* are usually aminoglycoside resistant. In cases of *Pseudomonas*-like infections of the eye, aminoglycosides are often the first-line therapy; therefore it is important to obtain the correct identification as quickly as possible and/or its antimicrobial susceptibility for appropriate treatment. *Delftia tsuruhatensis* has been associated with catheter-related bacteremia. This isolate was identified incorrectly as *D. acidovorans* with the VITEK 2 card; however, it was identified correctly with 16S rRNA sequencing. Disk diffusion susceptibility testing revealed the isolate to be susceptible to fluoroquinolones, carbapenems, third-generation cephalosporins, and piperacillin-tazobactam, but resistant to ampicillin, aminoglycosides, and colistin.

Weeksellaceae

About 15 genera, including *Bergeyella*, *Chryseobacterium*, *Elizabethkingia*, *Empedobacter*, *Weeksella*, and *Wautersiella*, are placed in the family Weeksellaceae. Members of the family are ubiquitous in soil and water and are not considered part of the normal human microbiota. Because isolates often contaminate hospital equipment, they can be important causes of nosocomial infections. Even though the organisms are weak fermenters, the reactions are usually delayed, and the isolates initially appear to be nonfermenters.

Most diseases produced by members of the Weeksellaceae are caused by *Elizabethkingia meningoseptica*. The infection typically presents as meningitis or septicemia in a newborn, especially in conjunction with prematurity. In adults, *E. meningoseptica* can cause pneumonia, endocarditis, bacteremia, and meningitis, especially in critically ill patients. There have been a few documented outbreaks of *E. meningoseptica* infections subsequent to the use of materials that had become contaminated with the organism. Tissue allograft material was found to be the cause of infection in two recipients during repair of their cruciate ligament; the allografts were

thought to have become contaminated during processing of the tissue. In 2011, the U.S. Food and Drug Administration (FDA) initiated a recall of povidone-iodine pads used for skin disinfection because they were found to be contaminated with *E. meningoseptica*. The bacteria produce acid from glucose, maltose, and mannitol. They hydrolyze esculin and are indole positive, and growth on MacConkey agar is variable.

The genus *Chryseobacterium* contains over 100 species. *Chryseobacterium indologenes* is the most frequently isolated species in this genus found in human specimens, although it is often considered insignificant when isolated in rare numbers or from only one medium or one specimen. It has, however, been linked to healthcare-associated infections, including bacteremia, usually in immunosuppressed patients or patients who have been receiving long-term antimicrobial therapy, and in ocular infections. Isolated cases of endophthalmitis have been reported to be caused by *Empedobacter brevis* following cataract surgery. The source was thought to be poor sterilization procedures.

Members of the genus *Wautersiella* have been isolated from blood and surgical wounds. Isolates closely resemble *E. brevis*. *Weeksella virosa* has been found in genitourinary specimens and will grow on modified Thayer-Martin medium or other media selective for *Neisseria gonorrhoeae*. *Bergeyella zoohelicum* has been isolated from cases of cellulitis, tenosynovitis, septicemia, pneumonia, and meningitis, particularly in association with dog and cat bite wounds, because it is part of their normal oral biota. However, there have been cases of bacteremia without any known animal exposures. *Weeksella* isolates are asaccharolytic, indole and oxidase positive, and fail to grow on MAC agar.

Most organisms in the family Weeksellaceae are nonmotile, and many species possess an intracellular pigment that can be salmon-pink or pale yellow (Fig. 21.14). On media with blood, a lavender-green discoloration of the agar may occur because of the proteolytic activity of the organisms. Some species release a characteristic fruity odor. Most isolates are DNase, oxidase, gelatin hydrolysis, and weakly indole positive (the more sensitive Ehrlich indole test is recommended over the Kovacs test). Microscopically, *E. meningosepticum* and *C. indologenes* are long, thin bacilli, often with bulbous ends.

Fig. 21.14 *Elizabethkingia meningoseptica*. Note the growth with yellow pigment on sheep blood agar (left) and absence of growth on MacConkey agar plate (right).

In vitro, most species are resistant to aminoglycosides and β -lactam antibiotics, but some species are susceptible to vancomycin, which is an unusual characteristic for gram-negative bacilli. However, one report of susceptibility testing of more than 50 isolates of *Chryseobacterium* spp. demonstrated reduced activity to vancomycin compared with what had been previously reported. Activity to SXT, fluoroquinolones, and piperacillin-tazobactam is often good. *Balneatrix* is resistant to clindamycin and vancomycin, unlike *E. meningoseptica*. *Weeksella* and *Bergeyella* spp. are susceptible to penicillin and other antimicrobial agents.

Methylobacterium* and *Roseomonas

The genus *Methylobacterium*, in the family Methylobacteriaceae, contains over 50 named species plus additional unnamed biovars. Isolates produce a characteristic pink to coral pigment and can use methanol as a sole source of carbon and energy. Epidemiologically, the *Methylobacterium* are isolated from soil, vegetation, sewage, water, and hospital nebulizers. They have also been recovered from clinical specimens such as throat swabs, bronchial washes, and even blood specimens. Clinically, these organisms have been reported to cause bacteremia, peritonitis, synovitis, and skin ulcers, usually in immunocompromised hosts. Contaminated tap water has been implicated as a cause of positive blood cultures in a patient receiving irrigations who had recently undergone bone marrow transplant. A leukemic patient who had undergone stem cell transplant was found to have bacteremia with *Methylobacterium fujisawaense*.

Methylobacterium mesophilicum and *M. zatmanii* are the two species usually isolated in clinical specimens. They prefer a lower temperature (25° to 35°C), produce distinctive large vacuolated pleomorphic rods, and are oxidase variable and motile with a polar flagellum. Oxidation of carbohydrates is weak. Isolates are slow growers, producing 1-mm dry, coral, or pink colonies in 4 to 5 days. They are often first seen on fungal media, such as Sabouraud dextrose agar, and do not grow as well on SBA, chocolate, modified Thayer-Martin, or buffered charcoal-yeast extract agars. No growth on MAC agar is typical.

The other pink-pigmented, nonfermentative bacilli are a group of bacteria now classified in the genus *Roseomonas*, in the family Acetobacteraceae. These bacteria have been isolated from the environment and clinical specimens, including blood, CSF, sputum, abscess, and wound specimens. In a review covering 10 years, 17 of 20 patients from whom *Roseomonas* spp. were isolated were considered to have true infection, primarily in immunocompromised patients. *R. mucosa* was the usual isolate, and catheter-related bloodstream infection was the most common infection seen. On Sabouraud dextrose agar, *Roseomonas* spp. produce pink, mucoid, almost runny colonies (Fig. 21.15); however, they do not appear black under long-wavelength ultraviolet light, as do *Methylobacterium* spp. *Roseomonas* spp. are nonvacuolated, coccoid bacteria, forming pairs and short chains. They are variable in the oxidase reaction, often weakly positive, and urease positive. Unlike *Methylobacterium* spp., species of *Roseomonas* will usually grow on MAC agar. Although uncommon isolates, they are the most common pink-pigmented, gram-negative, nonfermentative bacillus recovered in clinical laboratories.

Fig. 21.15 *Roseomonas* on sheep blood agar. Note the pink to red colonies.

Ralstonia and *Cupriavidus*

Ralstonia and *Cupriavidus* belong to the family Burkholderiaceae along with *Burkholderia* and numerous other genera. *Ralstonia pickettii* is the most common species of the seven in this genus isolated from humans. Isolates can be found contaminating sterile hospital fluids and, as such, may be isolated from specimens including urine, nasopharynx, abscess, wound, and blood specimens, usually as colonizers or contaminants. It has been linked to meningitis, endocarditis, and osteomyelitis. *R. pickettii* and *Ralstonia mannitolilytica* have been isolated from respiratory specimens of patients with CF and in non-CF patients as well. The significance is not always clear, although it appears that colonization increases in patients who are mechanically ventilated compared with patients who are not. *R. mannitolilytica* appears to be the *Ralstonia* species most often causing infections in patients with CF. A case of community-acquired lobar pneumonia and pulmonary abscess was described in a 65-year-old patient; the lung biopsy specimen and thoracentesis fluid grew *R. pickettii*, and symptoms resolved after cephalosporin and carbapenem were administered for 3 weeks.

R. pickettii isolates are slow growers, requiring more than 72 hours on primary cultures before colonies are visible. *R. pickettii* is oxidase and catalase positive (there are reports of rare catalase-negative strains), grows on MAC agar, reduces nitrate, oxidizes glucose and xylose, and is motile by means of a single polar flagellum. There are many species of *Ralstonia*, and definitive identification may require methods other than phenotypic methods, although there are even some problems with those.

Cupriavidus pauculus has been isolated from a number of aquatic environments and has been recognized as an opportunistic pathogen that can cause serious infections, including septicemia, peritonitis, abscesses, and tenosynovitis, most notably in immunocompromised patients. There was a pseudobacteremia cluster involving five patients, four adults in the emergency department and one neonate in the ICU. None appeared to have symptoms of a bloodstream infection. All isolates had the same molecular fingerprinting; environmental sources were presumed to have caused the contamination, although none were found. The unusual practice of moistening culturette swabs with tap water before the collection of microbiology samples led to an outbreak of *C. pauculus*

infection in an outpatient clinic in Columbus, Ohio. *C. pauculus* and *Cupriavidus gilardi* have also been isolated from patients with CF.

C. pauculus is a motile (peritrichous flagella), oxidase-positive, catalase-positive, asaccharolytic, gram-negative bacillus. Most strains grow on MAC agar. Isolates are resistant to aminoglycosides, ampicillin, and first- and second-generation cephalosporins. They are usually susceptible to quinolones, third-generation cephalosporins, piperacillin, and doxycycline, although not many isolates have been tested.

Shewanella

Shewanella is one of about four genera in the family Shewanellaceae. *Shewanella algae* and *S. putrefaciens*, though infrequent isolates and rarely pathogenic, have been recovered from various human specimens, including specimens from abscesses and traumatic ulcers, otitis media, ocular infections, osteomyelitis, peritonitis, and septicemia, but are usually present in mixed culture. Frequently, they probably represent colonization rather than infection. Environmental sources, such as stagnant water, natural gas (petroleum), brine, and spoiled dairy products, meat, and fish may contain *S. putrefaciens*. *S. algae* is more frequently isolated from clinical specimens than *S. putrefaciens*, whereas *S. putrefaciens* is more frequently isolated from environmental sources.

Colonies of *Shewanella* spp. are often mucoid and can produce a tan to brown pigment causing greenish discoloration of SBA. Both species are motile, ornithine decarboxylase and nitrate reductase positive, and produce profuse H_2S in TSIA, resembling H_2S producers of the order Enterobacterales. The positive oxidase test should differentiate *Shewanella* from the order Enterobacterales (except for *Plesiomonas*). *S. algae* requires NaCl (halophilic) and is asaccharolytic, whereas *S. putrefaciens* is nonhalophilic and saccharolytic. These organisms are usually susceptible to ampicillin, tetracycline, chloramphenicol, erythromycin, and the aminoglycosides, but resistant to penicillin and cefazolin.

Sphingomonas

Sphingomonas paucimobilis can be isolated from many water sources, including swimming pools, as well as from hospital equipment and laboratory supplies. The genus *Sphingomonas* contains over 100 species, but only two are believed to be clinically significant: *S. paucimobilis* and *S. parapaucimobilis*. Documented *S. paucimobilis* infections include peritonitis associated with CAPD, septicemia, meningitis, leg ulcers, empyema, and splenic and brain abscesses. *S. parapaucimobilis* has been isolated from sputum, urine, and vaginal specimens. Although isolates have been found to produce esterases, endotoxin, lipases, and phosphatases, inherent virulence is limited, and most isolates should be considered as colonizers or contaminants initially unless repeatedly isolated from a patient's samples. In a study of 55 documented infections with *S. paucimobilis* in Taiwan, 53% were community-acquired infections, and in this group almost 50% presented as bacteremia. In the hospital-associated infections, most presented with pneumonia.

The yellow-pigmented *S. paucimobilis* does not grow on MAC agar and requires more than 48 hours for culture on SBA (Fig. 21.16). Isolates are weakly oxidase positive (some strains

Fig. 21.16 *Sphingomonas paucimobilis* on sheep blood agar. Note the yellow colonies.

may be negative), motile at 18° to 22°C but not at 37°C, indole negative, and oxidizers. *S. parapaucimobilis* resembles *S. paucimobilis*, except that isolates of *S. parapaucimobilis* are H₂S positive by the lead acetate method, Simmon citrate positive, and DNase negative. *S. paucimobilis* isolates demonstrate variable resistance to antimicrobial agents, although most are susceptible to the aminoglycosides, tetracyclines, chloramphenicol, and SXT. Susceptibility to the third-generation cephalosporins (e.g., ceftazidime, ceftriaxone, ceftizoxime) and to the fluoroquinolones differs. Most isolates are resistant to colistin. They are susceptible to polymyxin B, which differentiates isolates from members of the genus *Sphingobacterium*, which they resemble. They are typically sensitive to vancomycin, which is unusual for gram-negative bacteria.

POINTS TO REMEMBER

- Nonfermenters will not acidify the butt of TSIA or KIA.
- Most nonfermenters are oxidase positive, a key test in differentiation from most members of the order Enterobacterales.
- Nonfermenters are environmental isolates that rarely cause disease in healthy humans.
- Nonfermenters can be more resistant to antimicrobial agents than members of the order Enterobacterales. There are specific methods and breakpoints available for many of the nonfermenters in the CLSI standards.
- The most common nonfermenters isolated in clinical microbiology laboratories are *P. aeruginosa*, *A. baumannii* complex, *S. maltophilia*, and *B. cepacia* complex.
- *Acinetobacter* spp. may retain the crystal violet stain resembling gram-positive bacteria.
- *Pseudomonas aeruginosa* produces several virulent factors leading to its pathogenicity, and many strains produce a fruity, grapelike odor.
- Phenotypic identification will not identify all nonfermenters; MALDI-TOF mass spectrometry or 16S rRNA DNA sequencing is required if confirmation is needed.
- The decision to identify many of the nonfermenters is based on the site from which they have been isolated, that is, whether they have been recovered from a normally sterile

site in pure culture or from a nonsterile site in which three or four other bacterial species are also present.

- Specimens from patients with CF often demonstrate a wide variety of nonfermentative bacilli and may require more definitive identification methods. The most common, however, is *P. aeruginosa*.
- Melioidosis is most common in areas of the world with tropical and subtropical climates. Most cases in the United States occur in persons returning from a country where the disease is endemic, although recent cases with no travel history have been reported.

LEARNING ASSESSMENT QUESTIONS

1. Which of the following characteristic clues can indicate the presence of a nonfermenter in the clinical laboratory?
 - a. Oxidase-positive reaction that can be weak
 - b. No acid production in the slant or butt of TSIA or KIA
 - c. Resistance to a variety of classes of antimicrobial agents
 - d. All of the above
2. What is the difference between nonfermentative and fermentative organisms based on carbohydrate utilization?
 - a. Nonfermenters are able to ferment sugars.
 - b. Nonfermenters are able to acidify the butt of TSI or KIA.
 - c. Fermenters are not able to acidify the butt of TSI or KIA.
 - d. Fermenters are able to metabolize carbohydrates.
3. Which of the following is the typical natural habitat of most nonfermenters?
 - a. All nonfermenters are part of the normal human biota.
 - b. Nonfermenters are never found in soil and water.
 - c. Most nonfermenters often exist in a moist or aquatic environment.
 - d. Nonfermenters are only found in hospital environments.
4. Which type of hospital-acquired infections do nonfermenters cause?
 - a. Urinary tract infections
 - b. Postsurgical wound infections
 - c. Septicemia
 - d. All of the above
5. Which of the following is a risk factor for diseases caused by nonfermentative gram-negative bacilli?
 - a. Immunosuppression
 - b. Foreign-body implantation
 - c. Trauma
 - d. All of the above
6. Which of the following is the most common and clinically significant nonfermenter associated with clinical infections?
 - a. *Acinetobacter baumannii*
 - b. *Stenotrophomonas maltophilia*
 - c. *Pseudomonas aeruginosa*
 - d. *Burkholderia* spp.
7. What are the four most common nonfermentative, gram-negative bacilli isolated in the clinical laboratory?
8. What are the typical susceptibility patterns of the most commonly isolated nonfermenters?
9. Which initial clues indicate that an isolate is a nonfermenter?
 - a. Nonfermenters will not grow on media selective for gram-negative bacilli.

- b. Nonfermenters are usually lactose-positive on media selective for gram-negative bacilli.
 - c. Nonfermenters will be oxidase-negative.
 - d. Nonfermenters will not produce an acid (yellow) butt in TSI or KIA.
10. How can *Pseudomonas aeruginosa* be differentiated from other fluorescent group pseudomonads?
 - a. Ability to grow at 42°C
 - b. Presence of a blue-green pigment diffusing through the medium
 - c. Grapelike odor
 - d. All of the above
 11. Which of the following is an identifying characteristic of *Acinetobacter* spp.?
 - a. Gram-positive coccobacillary organisms
 - b. Oxidase-positive
 - c. Have a bluish-purple appearance on MacConkey agar
 - d. Catalase negative
 12. Which nonfermenter is most commonly isolated from patients with cystic fibrosis?
 - a. *Burkholderia cenocepacia*
 - b. *Pseudomonas aeruginosa*
 - c. *Acinetobacter baumannii*
 - d. *Burkholderia multivorans*
 13. Blood cultures from a 45-year-old female patient who has been receiving treatment for breast cancer grow an oxidase-negative, motile, gram-negative bacillus. The organism grows well on a blood agar plate and produces clear, colorless colonies on MacConkey agar and on TSI, K/K reaction. Based on these characteristics, which of the following organisms should be suspected?
 - a. *Acinetobacter baumannii*
 - b. *Stenotrophomonas maltophilia*
 - c. *Pseudomonas aeruginosa*
 - d. *Burkholderia* spp.
 14. Which of the following organisms causes melioidosis, a glanders-like disease in humans and animals?
 - a. *Burkholderia pseudomallei*
 - b. *Pseudomonas aeruginosa*
 - c. *Acinetobacter baumannii*
 - d. *Burkholderia multivorans*
 15. An organism is isolated from the endotracheal tube of a patient receiving chemotherapy. The gram-negative coccobacillus grows on a blood agar plate and produces clear, colorless colonies on MacConkey agar. The isolate is nonmotile, oxidase negative, and biochemically inactive. Which of the following organisms should be suspected?
 - a. *Burkholderia pseudomallei*
 - b. *Pseudomonas aeruginosa*
 - c. *Acinetobacter lwoffii*
 - d. *Stenotrophomonas maltophilia*

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Characterize anaerobic bacteria, including why they are sensitive to oxygen.
2. Describe where anaerobes might be found in the environment and human body.
3. Differentiate the various types of anaerobes with regard to atmospheric requirements (i.e., obligate anaerobes, facultative anaerobes, and aerotolerant anaerobes).
4. Discuss how anaerobes, as part of endogenous microbiota, initiate and establish infection.
5. Describe the endogenous anaerobes commonly involved in human infections and the types of infections with which they are most often associated.
6. Assess specimens that are acceptable and unacceptable for anaerobic culture.
7. Describe the atmospheric requirements, isolation media, and identification systems used for the culture and isolation of anaerobes.
8. Given the signs and manifestations of an anaerobic infection, identify the most probable causative agent of:
 - Wound botulism
 - Tetanus
 - Gas gangrene
 - Actinomycosis
 - Pseudomembranous colitis
 - Bacterial vaginosis
9. Compare the methods available for cultivation of obligate anaerobes.
10. Compare the microscopic and colony morphology of anaerobic isolates.
11. Evaluate the different systems used to grow obligate anaerobes in the clinical microbiology laboratory.
12. Given the results of key biochemical laboratory tests, identify the most likely anaerobic isolate.

13. Evaluate the laboratory methods for the diagnosis of *Clostridioides difficile* infection.
14. Name the pigment-producing anaerobic bacteria.
15. Discuss the acceptable susceptibility methods for testing of anaerobes for antimicrobial susceptibility and when anaerobe susceptibility testing should be performed.
16. Describe the antimicrobial agents to be tested for susceptibility and resistance patterns of anaerobic organisms.
17. Describe the five major approaches to treat anaerobe-associated diseases: antimicrobial therapy, surgical therapy, hyperbaric oxygen therapy, administration of antitoxins, and fecal microbiota transplant.

KEY TERMS

Actinomycosis	Enteritis necroticans
Aerotolerance test	Exogenous anaerobe
Aerotolerant anaerobe	Facultative anaerobe
Anaerobe	Hydroxyl radical
Anaerobic chamber	Microaerophilic
Bacterial vaginosis (BV)	Myonecrosis
Botulism	Obligate anaerobe
Capnophilic	Pseudomembranous colitis
Catalase	Superoxide anion
<i>Clostridioides difficile</i>-associated disease (CDAD)	Superoxide dismutase
Endogenous microbiota	Tetanus

Case in point

A 45-year-old male patient who worked as a farmer was admitted to the hospital for complications resulting from a tractor accident that caused traumatic injury to his left leg. The patient's leg was painful, bluish, and edematous. An x-ray revealed pockets of gas in the tissue. A complete blood count revealed a marked increase in the levels of neutrophils and a total white blood cell count of 33,000/mL. A Gram-stained smear of the wound specimen revealed numerous large, rectangular-shaped, gram-positive bacilli, with no spores and very few leukocytes. The patient was immediately scheduled for surgical debridement and was given a broad-spectrum antimicrobial agent. Within 24 hours, anaerobic cultures grew gram-positive rods, with a double zone of β hemolysis surrounding the colonies on sheep blood agar (SBA) incubated anaerobically.

Issues to consider

After reading the patient's case history, consider:

- The clinical significance of anaerobes in human infections
- Indications of an anaerobic infection
- The importance of proper selection, collection, transport, and processing of anaerobic specimens
- Various anaerobes that may be found in different specimen types
- Extent of anaerobe identification
- When and how to perform susceptibility testing of anaerobes

Anaerobic bacteria are important in human and veterinary medicine because they play a role in serious and potentially fatal infections and intoxications. They are involved in infectious

processes in almost every organ or tissue of the body and consequently can be recovered from most clinical specimens. This chapter discusses how anaerobes differ from aerobic bacteria, the importance of anaerobes as endogenous microbiota and their role as disease-causing agents, the proper techniques for recovery and identification of anaerobes, susceptibility testing of anaerobic isolates, and treatment of anaerobic infections.

Important concepts in anaerobic bacteriology

Anaerobes defined

An **anaerobe** is a bacterium able to replicate in the absence of oxygen. To recover all potential pathogens, the clinical microbiology laboratory must use a variety of atmospheric conditions for culturing bacteria (Table 22.1). Ambient air contains approximately 21% oxygen and 0.04% carbon dioxide (CO₂). Obligate, or strict, aerobes require oxygen for metabolism, and they can grow well in an ambient air incubator. **Capnophilic** organisms, such as *Capnocytophaga*, grow best when the concentration of CO₂ is increased to the range of 5% to 10% in a CO₂ incubator. This increase in CO₂ concentration reduces the oxygen concentration to 15%, which is still sufficient to allow aerobic organisms to replicate. **Microaerophilic** organisms, such as *Campylobacter*, require the oxygen concentration to be reduced to 5% or less. **Facultative anaerobes**, such as *Escherichia coli* and *Staphylococcus aureus*, preferentially use oxygen as an electron acceptor if it is available but can grow in the absence of oxygen, albeit at a slower rate.

Table 22.1 Classification of microorganisms on the basis of their relationship to oxygen and carbon dioxide

Category	Requirement	Examples
Obligate aerobe	15%–21% O ₂ (as found in a CO ₂ incubator or ambient air)	Mycobacteria, fungi
Microaerophile	5% O ₂	<i>Campylobacter</i> , <i>Helicobacter</i>
Facultative anaerobe	Multiplies well in the presence or absence of O ₂	Enterobacterales, most staphylococci
Aerotolerant anaerobe	Reduced concentrations of O ₂ (anaerobic system and microaerophilic environments)	Most strains of streptococci, <i>Propionibacterium</i> , <i>Lactobacillus</i> , some <i>Clostridium</i>
Obligate anaerobe	Strict anaerobic environment (0% O ₂)	Most <i>Bacteroides</i> spp., many species of <i>Clostridium</i> , <i>Eubacterium</i> , <i>Fusobacterium</i> , <i>Peptostreptococcus</i> , <i>Porphyromonas</i>
Capnophile	5%–10% CO ₂	Some anaerobes, <i>Neisseria</i> , <i>Capnocytophaga</i>

Modified from Engelkirk, P. G., et al. (1992). *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.

Anaerobes differ in their response to oxygen. Some anaerobes are killed almost immediately in the presence of oxygen (e.g., *Clostridium novyi*). These are referred to as **obligate**, or **strict, anaerobes**. To grow obligate anaerobes, the laboratory must use oxygen-free growth conditions. This can be accomplished by a variety of mechanisms (see the “Processing Clinical Samples for Recovery of Anaerobic Pathogens” section later in this chapter). Other anaerobes can survive a short exposure to oxygen but typically will not be able to perform metabolic processes unless placed into an anaerobic environment. These organisms are referred to as **aerotolerant**, or **moderate, anaerobes**. Many anaerobic pathogens encountered in the clinical microbiology laboratory fall into this group (e.g., *Bacteroides fragilis*).

Why some organisms are anaerobes

Molecular oxygen can be toxic to some anaerobes, but substances produced when oxygen becomes reduced through metabolic processes are even more toxic. During oxidation-reduction reactions that occur during normal cellular metabolism, molecular oxygen is reduced to **superoxide anion** (O_2^-) and hydrogen peroxide (H_2O_2) in a stepwise manner by the addition of electrons, as shown in the following equations:

Furthermore, one hypothesis of oxygen toxicity proposes that the superoxide anion reacts with hydrogen peroxide in the presence of iron (Fe^{3+}/Fe^{2+}) to generate the **hydroxyl radical** ($\cdot OH$). This short-lived molecule is the most potent biological oxidant known. The reaction between the hydroxyl radical and superoxide anion forms singlet oxygen, which is also damaging to cells. Together, these toxic compounds are detrimental to cell components such as proteins and nucleic acids. It is obvious that cells need a way to remove these harmful molecules if they are to survive in the presence of oxygen. Strict aerobic and facultative anaerobic bacteria that use oxygen have the enzymes **superoxide dismutase** and/or **catalase** to protect them from superoxide anions and their toxic derivatives, as shown in the following equations:

Superoxide dismutase converts the superoxide anion to oxygen and hydrogen peroxide. Hydrogen peroxide can be toxic to cells but not to the degree of the superoxide anion or hydroxyl radical. Hydrogen peroxide will diffuse out from the cell, but many organisms also possess the enzyme catalase, which breaks hydrogen peroxide down to oxygen and water, thereby negating its toxic effect. Because the hydroxyl radical is a product of the further reduction of the superoxide anion, elimination of the superoxide anion by superoxide dismutase will inhibit the formation of the hydroxyl radical.

Anaerobes, on the other hand, are particularly susceptible to these toxic derivatives of oxygen because they lack the protective enzymes superoxide dismutase and/or catalase, or the enzymes are present in low concentrations. Extended

exposure to oxygen results in cell death for strict anaerobes and cessation of growth for oxygen-tolerant anaerobes. Strict anaerobes also might require an environment that has a low oxidation-reduction (redox) potential. This may be in part because certain enzymes that are essential for bacterial growth require fully reduced sulfhydryl ($-SH$) groups to be active. Reducing agents such as thioglycollate, cysteine, and dithiothreitol often are added to microbiological media to obtain a low redox potential. In vivo, bacteria have a tendency to lower the redox potential at their site of growth. Consequently, anatomic sites colonized with mixtures of organisms, such as those found on mucosal surfaces, frequently provide favorable conditions for the growth of obligate anaerobes.

Where anaerobes are found

In a world in which oxygen abounds, anaerobes are found only in specific ecologic niches. They can be found in soil, in freshwater and saltwater sediments, and as components of the **endogenous microbiota** of humans and other animals. Anaerobes that exist outside the bodies of animals are referred to as **exogenous anaerobes**; the infections they cause are termed *exogenous infections*. Conversely, anaerobes that exist inside the body (endogenous microbiota) are termed *endogenous anaerobes* and are the source of endogenous infections.

Exogenous anaerobic infections are usually caused by gram-positive, spore-forming bacilli belonging to the genus *Clostridium*. Clostridia initiate infection when spores are ingested by way of contaminated food or gain access to the body through open wounds contaminated with soil. However, the anaerobes most frequently isolated from infectious processes in humans are those of endogenous origin. Table 22.2 shows endogenous anaerobes commonly encountered in human infections. Endogenous anaerobes can contribute to an infectious disease in any anatomic site of the body if suitable conditions exist for colonization and penetration of the bacteria.

Although many different species of anaerobes can be isolated from human clinical specimens, the number of species routinely isolated is relatively small. Table 22.3 lists the anaerobes most frequently recovered from clinical specimens at a university medical center, including members of the *B. fragilis* group, *Porphyromonas* and *Prevotella* spp., anaerobic cocci (e.g., peptostreptococci), and *Propionibacterium* spp. A pathogenic anaerobe frequently encountered in healthcare-associated infection is *Clostridioides difficile*, a cause of antibiotic-associated diarrhea.

Case check 22.1

In the Case in Point, the infecting organism was likely *Clostridium perfringens*, which can be found as exogenous microbiota in soil. The wound caused by the tractor accident was likely contaminated by soil containing the organism or its spores. The trauma to the legs following the accident allowed the organism to penetrate the skin surface.

Anaerobes at specific anatomic sites

Anaerobes outnumber aerobes on mucosal surfaces, such as the linings of the oral cavity, gastrointestinal (GI) tract, and genitourinary (GU) tract. These heavily colonized surfaces

are the usual portals of entry into the tissues and bloodstream for endogenous anaerobes. Under ordinary circumstances, microorganisms that are members of the microbiota do not cause disease, and many actually can be beneficial. However,

when some of these organisms gain access to usually sterile body sites, such as the bloodstream, brain, and lungs, they can cause serious or even fatal infections.

Knowledge of the composition of the microbiota at specific anatomic sites is useful for predicting the microorganisms most likely to be involved in infectious processes that arise at or adjacent to those sites. Table 22.4 summarizes the variety of endogenous anaerobes that may be found at specific body sites. Finding site-specific organisms at a distant and/or unusual site can serve as a clue to the underlying origin of an infectious process. For example, the isolation of oral anaerobes from a brain abscess may suggest invasion from the oral cavity, perhaps caused by poor dentition.

Skin

Indigenous members of the skin microbiota include anaerobes that colonize the sebaceous glands and hair follicles. *Cutibacterium acnes* is frequently isolated from blood cultures, but its presence often represents contamination from the patient's skin resulting from poor site preparation during the venipuncture. Nevertheless, *C. acnes* is considered an opportunistic pathogen and has been associated with cases of endocarditis, surgical wounds, and prosthetic joint infections. Other anaerobes found on the skin include gram-positive cocci (e.g., *Peptostreptococcus*). Superficial wound or abscess specimens aspirated by needle and syringe are much better specimens for anaerobic bacteriology than material collected by swabs; the latter often are contaminated with skin microbiota.

Respiratory tract

Of the bacteria present in saliva, nasal washings, and gingival and tooth scrapings, 90% are anaerobes. Gram-negative anaerobic bacilli (*Prevotella*, *Porphyromonas*, and *Fusobacterium*) and anaerobic cocci are the anaerobes occurring in the largest numbers. These anaerobes should be suspected as participants in any infectious process occurring in the oral cavity and in suspected cases of aspiration pneumonia. In addition,

Table 22.2 Endogenous anaerobes commonly involved in human infections

Infection	Anaerobe
Actinomycosis	<i>Actinomyces israelii</i> , other <i>Actinomyces</i> spp.
Antibiotic-associated diarrhea; pseudo-membranous colitis	<i>Clostridioides difficile</i>
Bacteremia	<i>Bacteroides fragilis</i> group, fusobacteria, clostridia, AGPC
Brain abscess	<i>Bacteroides</i> spp., <i>Prevotella</i> spp., <i>Porphyromonas</i> spp., <i>Fusobacterium</i> spp., <i>Clostridium</i> spp. (these infections are often polymicrobial)
Infections of the female genitourinary tract	AGPC, <i>Bacteroides</i> spp., <i>Clostridium</i> spp., <i>Prevotella bivia</i> , <i>Prevotella disiens</i> , <i>Porphyromonas</i> spp., <i>Actinomyces israelii</i> (IUD associated)
Intraabdominal infections, liver abscess, peritonitis, perineal and perirectal infections	<i>B. fragilis</i> group, other <i>Bacteroides</i> spp., <i>Fusobacterium</i> spp., <i>Clostridium perfringens</i> , other <i>Clostridium</i> spp., AGPC (frequently polymicrobial)
Myonecrosis	<i>C. perfringens</i> , <i>Clostridium novyi</i> , <i>Clostridium septicum</i> (80%–95% of the cases)
Head and neck infections, e.g., sinus, otitis media, dental abscesses, gingivitis, periodontitis	AGPC, <i>Porphyromonas</i> spp., <i>Fusobacterium</i> spp. (often polymicrobial)
Aspiration pneumonia, pleuropulmonary infections	<i>Porphyromonas</i> spp., <i>Fusobacterium nucleatum</i> , <i>Prevotella</i> spp., AGPC, <i>B. fragilis</i> group, <i>Actinomyces</i> spp.

AGPC, Anaerobic gram-positive cocci; IUD, intrauterine device.

Table 22.4 Endogenous anaerobes of various anatomic sites

Site	Anaerobes
Skin	<i>Propionibacterium</i> , peptostreptococci
Upper respiratory tract	AGPC, <i>Actinomyces</i> , <i>Propionibacterium</i> , <i>Campylobacter</i> , <i>Fusobacterium</i> , <i>Prevotella</i> , <i>Veillonella</i>
Oral cavity	<i>Actinomyces</i> , <i>Eubacterium</i> /Eggerthella, AGPC, <i>Campylobacter</i> , <i>Fusobacterium</i> , <i>Prevotella</i> , <i>Bifidobacterium</i> , <i>Porphyromonas</i> , <i>Veillonella</i>
Intestine	<i>Bifidobacterium</i> , <i>Eubacterium</i> /Eggerthella, <i>Clostridium</i> , AGPC, <i>Bacteroides fragilis</i> group, <i>Parabacteroides</i> , <i>Bilophila</i> , <i>Campylobacter</i> , <i>Fusobacterium</i> , <i>Porphyromonas</i> , <i>Prevotella</i> , <i>Sutterella</i> , <i>Veillonella</i>
Genitourinary tract	AGPC, <i>Bifidobacterium</i> , <i>Fusobacterium</i> , <i>Lactobacillus</i> , <i>Mobiluncus</i> , <i>Prevotella</i> , <i>Veillonella</i>

AGPC, Anaerobic gram-positive cocci.
Modified from Jouseimies, H. R., et al. (2002). *Wadsworth-KTL anaerobic bacteriology manual* (6th ed.). Belmont, CA: Star Publishing.

invasion through the oral mucosa should be suspected whenever oral anaerobes such as *Fusobacterium nucleatum* and *Porphyromonas* are recovered from the bloodstream or from abscesses located far from the oral cavity.

Gastrointestinal tract

It is estimated that 500 to 1000 different species of bacteria live in the GI tract. Microbiota studies have found that anaerobes outnumber facultative anaerobes by a factor of 1000:1. Although *B. fragilis* is the most common species of anaerobic bacteria isolated from soft tissue infections and bacteremia, it accounts for less than 1% of the human intestinal biota. Other members of the *B. fragilis* group, such as *B. vulgatus*, *B. thetaiotaomicron*, and *Parabacteroides distasonis*, are among the most common species of bacteria isolated from human feces. Other species commonly inhabiting the GI tract include species of *Bifidobacterium*, *Clostridium*, *Eubacterium*, and anaerobic gram-positive cocci. Any infection in the peritoneal cavity would likely be caused by organisms that have escaped from the GI tract.

Genitourinary tract

Although anaerobic bacteria colonize the distal urethra, they are not considered to be a cause of uncomplicated urinary tract infections. Similarly, 50% of the bacteria in cervical and vaginal secretions are anaerobes. These include anaerobic cocci, *Fusobacterium*, *Prevotella*, *Bacteroides*, and *Lactobacillus*. For this reason, GU swabs and voided or catheterized urine specimens are unacceptable for anaerobic bacteriology because recovery of these organisms would not distinguish whether they were present as pathogens or as endogenous microbiota.

Factors that predispose patients to anaerobic infections

The precise mechanisms whereby anaerobic bacteria cause disease are not always known. Like other pathogenic bacteria, anaerobes can produce a variety of virulence factors. Toxins, molecules that break down tissue, capsules that inhibit phagocytosis by macrophages, and adherence factors that aid in attachment to mucosal surfaces are thought to play a role in pathogenicity (Table 22.5). Generally, infectious diseases involving anaerobic bacteria follow some type of trauma to protective barriers such as the skin and mucous membranes. Trauma at these sites allows anaerobes of the endogenous biota (or in some cases, soil anaerobes) to gain access to deeper tissues. Any condition causing vascular stasis, decreased blood flow, prevents oxygen from entering a particular site, which results in an environment conducive to growth and multiplication of any anaerobe that might be present at that site. Similar results can occur in the presence of tissue necrosis and when the redox potential in tissue is decreased. Box 22.1 lists examples of conditions that may predispose a patient to anaerobic infections.

Indications of anaerobe involvement in human disease

Infectious processes involving anaerobes are usually purulent, with many polymorphonuclear leukocytes present. However, the absence of leukocytes does not rule out the possibility that anaerobes are contributing to the process because some anaerobes, such as *Clostridium perfringens*, produce enzymatic virulence factors that destroy neutrophils, macrophages, and other cells.

Table 22.5 Potential virulence factors of anaerobic bacteria		
Potential virulence factor	Possible role	Anaerobes known or thought to possess
Polysaccharide capsules	Promotes abscess formation; antiphagocytic function	<i>Bacteroides fragilis</i> , <i>Porphyromonas gingivalis</i>
Adherence factors	Fimbriae, fibrils enable organisms to adhere to cell surfaces	<i>B. fragilis</i> , <i>P. gingivalis</i>
Clostridial toxins, exoenzymes		
Collagenases	Catalyze the degradation of collagen	Certain <i>Clostridium</i> spp.
Cytotoxins	Toxic to specific types of cells	<i>Clostridioides difficile</i>
DNases	Destroy DNA	Certain <i>Clostridium</i> spp.
Enterotoxins	Toxic to cells of the intestinal mucosa	<i>C. difficile</i>
Hemolysins	Lyse red blood cells liberating hemoglobin	Certain <i>Clostridium</i> spp.
Hyaluronidase	Catalyzes the hydrolysis of hyaluronic acid, the cement substance of tissues	Certain <i>Clostridium</i> spp.
Lipases	Catalyze the hydrolysis of ester linkages between fatty acids and glycerol of triglycerides and phospholipids	Certain <i>Clostridium</i> spp.
Neurotoxins (e.g., botulinum toxin, tetanospasmin)	Destroy or disrupt nerve tissue	<i>Clostridium botulinum</i> , <i>Clostridium tetani</i>
Phospholipases	Catalyze the splitting of host phospholipids (lecithinase)	Certain <i>Clostridium</i> spp.
Proteases	Split host proteins by hydrolysis of peptide bonds	Certain <i>Clostridium</i> spp.
DNA, Deoxyribonucleic acid; DNases, deoxyribonucleases.		

BOX 22.1 Conditions that predispose individuals to anaerobe-associated infections or diseases

Vascular disease
 Presence of a foreign body
 Malignancy
 Immune deficiency
 Surgery
 Colitis
 Diabetes mellitus
 Human or animal bite wounds
 Aspiration of oral contents into the lungs after vomiting
 Tooth extraction, oral surgery, or traumatic puncture of the oral cavity
 Gastrointestinal tract surgery or traumatic puncture of the bowel
 Genital tract surgery or traumatic puncture of the genital tract
 Introduction of soil into a wound

BOX 22.2 Indications of involvement of anaerobes in infectious processes

Infection in close proximity to a mucosal surface
 Presence of foul odor
 Presence of large quantity of gas
 Presence of black color (necrosis) or brick red fluorescence
 Presence of "sulfur granules"
 Septic thrombophlebitis
 Bacteremia or endocarditis with no growth on aerobic cultures
 Clinical conditions predisposing to anaerobic infections, see [Box 22.1](#)

[Box 22.2](#) lists indications of anaerobe involvement in infectious processes. Although any of these indicators should alert the physician to the possible involvement of anaerobes, most are not specific for anaerobes. For example, large quantities of gas in the specimen might be caused by gas-producing organisms such as *E. coli* or a mixture of enteric bacteria other than anaerobes. Similarly, the foul odor usually associated with specimens containing anaerobes could be absent. Many of the infectious processes involving anaerobes are polymicrobial, consisting of mixtures of obligate anaerobes or mixtures of obligate or aerotolerant anaerobes and facultative organisms. A symbiotic relationship between facultative anaerobes and obligate anaerobes frequently exists in polymicrobial infections, which can contribute to an infectious disease. In these situations, facultative anaerobic bacteria consume oxygen and reduce the oxygen concentration, thus enhancing the growth of obligate anaerobic bacteria.

Frequently encountered anaerobes and their associated diseases

Taxonomically, anaerobic bacteria encountered in human clinical specimens may be divided into gram-negative and gram-positive genera. Anaerobic gram-positive bacilli can be further divided between those organisms capable of forming endospores (spore formers) and those unable to form spores (non-spore formers). The presence or absence of spores, coupled with the microscopic morphology on Gram-stained smears and colony morphology of culture isolates, can be helpful in making

a presumptive identification of anaerobic bacteria and determining the appropriate identification tests to be performed.

As with other areas of clinical microbiology, the use of molecular methods rather than phenotypic characteristics to determine taxonomic placement of an organism has resulted in an explosion of taxonomic changes. It is beyond the scope of this chapter to list all of the current names of rarely encountered anaerobes. Instead, this discussion will concentrate on the important anaerobes most likely to be encountered in specimens submitted to the clinical microbiology laboratory.

Gram-positive, spore-forming anaerobic bacilli

All spore-forming anaerobic bacilli are classified in the genera *Clostridium* or *Clostridioides* and are collectively termed *clostridia*. Although all clostridia are capable of producing spores, some species do so readily, whereas others require extremely harsh conditions. Spores are often not observed in Gram-stained smears of clinical specimens containing clostridia or in smears of colonies from an agar plate unless the culture has been incubated for many days. It is sometimes necessary to use heat or alcohol shock to induce sporulation.

Clostridia can be grouped according to the location of the endospore within the cell. Spores are described as *terminal* when they are located at the end of the bacterial cell and *subterminal* when the spore is found at a location other than the end of the cell. Terminal spores typically cause swelling of the cell. [Fig. 22.1](#) shows a clostridial species that produces terminal spores and a clostridial species that produces subterminal spores. Spores located in the center of the cell are called *central spores*.

Clinical infections

Clostridium spp. are frequently encountered in exogenous anaerobic infections or intoxications. Clostridia or their toxins usually gain access to the body through ingestion or open wounds that have become contaminated with soil. Clostridia cause classic diseases such as tetanus, gas gangrene (myonecrosis), botulism, and food poisoning (foodborne intoxication). In tetanus, gas gangrene, and wound botulism, clostridial spores enter through open wounds and germinate in vivo. The vegetative bacteria then multiply and produce toxins. In foodborne disease caused by *C. perfringens*, organisms are acquired through the consumption of contaminated food that has been improperly stored. Almost any *Clostridium* spp. can cause wound or abscess infection, usually as part of mixed biota, and most can be isolated from the blood in cases of bacteremia. One clostridial infection of endogenous origin is antibiotic-associated pseudomembranous colitis caused by *C. difficile*.

***Clostridium perfringens* food poisoning**

C. perfringens is associated with two types of food poisoning: type A, a relatively mild and self-limiting GI illness, and type C, a more serious but rarely seen disease. *C. perfringens* foodborne disease usually follows the ingestion of large numbers of enterotoxin-producing strains in contaminated food. *C. perfringens* lacks the ability to produce a number of essential

Fig. 22.1 Classification of some clinically encountered clostridia by endospore location. **A**, Gram-stained appearance of terminal spores of *Clostridium tetani* ($\times 1000$). **B**, Gram-stained appearance of subterminal spores of *Clostridium sordellii* ($\times 1000$). (Courtesy S.L. Bartley, J.D. Howard, and R. Simon, Centers for Disease Control and Prevention, Atlanta, GA.)

amino acids, so meats and gravies are commonly implicated in outbreaks. Foods are often heated, which kills vegetative bacteria, but the spore-forming clostridia survive. Improperly stored food allows germination of the spores and growth of vegetative bacteria. Food poisoning caused by *C. perfringens* type A results from an enterotoxin linked to sporulation. After an 8- to 30-hour incubation period, the patient experiences diarrhea and cramping abdominal pain for about 24 hours. Other than fluid replacement, therapy is usually unnecessary.

C. perfringens type C food poisoning (**enteritis necroticans**) is associated with strains that produce β -toxin and, less commonly, α -toxin. After an incubation period of at least 5 to 6 hours, symptoms begin as an acute onset of severe abdominal pain and diarrhea, which is often bloody, and may be accompanied by vomiting. Early symptoms are followed by necrotic inflammation of the small intestines, at times leading to bowel perforation. Without treatment, the disease is often fatal; even with treatment, the fatality rate is 15% to 25%. In general, the clinical microbiology laboratory usually does not have a role in recovering *C. perfringens* from food or feces during outbreaks unless serving a public health function.

Botulism

Foodborne **botulism** results from the ingestion of preformed botulinum toxin, produced in food by *C. botulinum*. Although there are seven antigenically distinct botulinum toxins (A to G), only types A, B, and E are associated with human disease. Botulinum toxin is an extremely potent neurotoxin; only a small amount produces death. Botulinum toxin attaches to the neuromuscular junction and prevents the release of acetylcholine (a neurotransmitter) from nerve cells, which results in flaccid paralysis and death. Botulinum toxin type A (Botox) is also used medically to treat strabismus (crossing eyes) and chronic migraines, and as a beauty enhancer by temporarily improving facial wrinkles.

The food sources involved commonly in botulism include home-canned vegetables, home-cured meat such as ham, fermented fish, and other preserved foods. Clinical manifestations develop as early as 2 hours or as late as 8 days following ingestion of food containing the botulinum toxin. The toxin is absorbed through the small intestine and enters the systemic circulation to reach the nervous system. Weakness and paralysis are the main features of botulism. Double or blurred vision, impaired speech, and difficulty swallowing are also commonly seen. Respiratory paralysis may occur in severe cases. Treatment of foodborne botulism involves the use of

antitoxin and supportive care. Infant botulism, unlike that in adults, follows the ingestion of *C. botulinum* spores. The food most commonly associated with infant botulism is honey contaminated with *C. botulinum* spores. Once ingested, the spores germinate, and the vegetative cells colonize the colon and subsequently produce toxin.

Wound botulism is the result of contamination of wounds with spores of *C. botulinum*, which germinate; the vegetative cells multiply and produce toxins. Clinical manifestations of wound botulism are similar to those of foodborne intoxication. Botulism toxin and *C. botulinum* are considered potential bioterrorism agents; laboratorians or physicians are required to notify public health laboratories if *C. botulinum* is isolated or if a case of botulism is suspected. See [Chapter 30](#) for a discussion of *C. botulinum* as a bioterrorism agent. Many clinical laboratories consider the isolation of *C. botulinum* a critical result, requiring that the nursing unit or physician be notified immediately. In 2018, the Centers for Disease Control and Prevention (CDC) reported 18 cases of foodborne botulism, 162 cases of infant botulism, and 61 cases of wound botulism infections. All cases of wound botulism were reported in individuals who injected drugs.

Tetanus

The clinical manifestations of **tetanus** are attributed to the neurotoxin tetanospasmin produced by *Clostridium tetani*. Tetanospasmin acts on neurons, preventing the release of inhibitory and excitatory neurotransmitters. This results in a spastic type of paralysis, with continuous muscular spasms leading to trismus (lockjaw), risus sardonicus (distorted grin), and difficulty breathing.

Tetanus occurs when spores in the environment enter the skin through puncture wounds. The spores germinate into vegetative cells that produce tetanospasmin. Symptoms usually appear approximately 7 days after the injury, but the incubation period can range from 3 to 21 days. The length of incubation is related to the distance from the injury to the central nervous system. Clinical manifestations include muscular rigidity, usually in the jaw, neck, and lumbar region. Difficulty swallowing results from muscular spasms in the pharyngeal area. Rigidity of the abdomen, chest, back, and limbs may also occur. As a result of the widespread use of the diphtheria-tetanus-acellular pertussis (DTaP) vaccine, tetanus is no longer a common disease in the United States; only 33 cases and 2 deaths were reported to the CDC in 2017. Therapy for tetanus requires injection of antitoxin, muscle relaxants, and

intensive therapy. Although most treated patients completely recover, long-term disability and even death can occur.

Myonecrosis

Myonecrosis, or gas gangrene, usually occurs when organisms contaminate wounds, through trauma or surgery. *C. perfringens*, *C. histolyticum*, *C. septicum*, *C. novyi*, and *C. bifermentans* have all been associated with myonecrosis. *C. perfringens*, however, is the most common cause. Under favorable conditions, the organisms are able to grow, multiply, and release potent exotoxins. In gas gangrene, exotoxins such as α -toxin produced by *C. perfringens* cause necrosis of the tissue and allow deeper penetration by the organisms.

α -Toxin is a lecithinase (phospholipase C) produced by all strains of *C. perfringens*. Clinical manifestations of myonecrosis include pain and swelling in the affected area. Bullae (fluid-filled blisters), serous discharge, discoloration, and tissue necrosis are observed. The onset and spread of myonecrosis can be rapid, and extensive surgical debridement of the necrotic tissue is often required. If treatment is delayed, amputation of the affected limb is not uncommon.

Case check 22.2

The patient's infection in the Case in Point is a typical scenario of gas gangrene (myonecrosis) caused by *C. perfringens*. The tissue exhibited marked necrosis, and gas pockets were noted in the tissue. Rapid surgical debridement is necessary for patient treatment.

Bacteremia

Many of the clostridia have been recovered from blood cultures, but *C. perfringens* is the most common. When *C. septicum* is present in the bloodstream, it is often a marker organism for a malignancy in the GI tract. *C. bifermentans* and *C. tertium* have also been isolated from blood cultures from patients with serious underlying disease.

Clostridioides difficile-associated disease

C. difficile is the most common but not the sole cause of antibiotic-associated diarrhea and **pseudomembranous colitis**, also referred to as ***C. difficile*-associated disease (CDAD)**. This organism is part of the GI biota in about 5% of individuals, although the colonization rate in patients in long-term care facilities, such as nursing homes and rehabilitation facilities, can reach 20% of the population. Following antimicrobial therapy, many bowel biota organisms other than *C. difficile* are killed, thus allowing *C. difficile* to multiply with less competition and produce high levels of two toxins: toxin A, an enterotoxin, and toxin B, a cytotoxin. Bloody diarrhea with associated necrosis of colonic mucosa is seen in patients with pseudomembranous colitis. *C. difficile* is a common cause of healthcare-associated infections. The organism is frequently transmitted among hospitalized patients and is present occasionally on the hands of hospital personnel. Diarrhea caused by *C. difficile* is being seen with increasing frequency in outpatients who have received antimicrobial therapy.

From 2000 to 2015, the incidence of *C. difficile* infections in humans increased in the United States and throughout Europe.

However, the CDC reported a slight decrease in total *C. difficile* infections in 2016 and 2017, with a slight increase in community-acquired cases. In 2017, an estimated 223,900 healthcare-associated *C. difficile* infections and 12,800 deaths occurred. Overall, an estimated 476,000 cases occurred in 2017.

Gram-positive, non-spore-forming anaerobic bacilli

Gram-positive, non-spore-forming anaerobic bacilli have undergone considerable taxonomic revision in recent years. In general, the group can be divided into two phyla, the Actinobacteria and the Firmicutes. Important clinical genera of the Actinobacteria include *Actinomyces*, *Bifidobacterium*, *Eggerthella*, *Mobiluncus*, and *Propionibacterium*. The Firmicutes include many genera, but *Lactobacillus* is the only member encountered on a routine basis in the clinical microbiology laboratory. All of these organisms are found as part of the endogenous microbiota of humans and can be considered opportunistic pathogens. The microscopic morphology of these organisms is varied, ranging from very short rods to long, branching filaments.

Clinical infections

Actinomycosis

Actinomycosis is a chronic, granulomatous, infectious disease characterized by the development of sinus tracts and fistulae, which erupt to the surface and drain pus that may contain so-called *sulfur granules*, dense clumps of bacteria that may be colored. Examinations of wet mounts and Gram-stained preparations of pus from draining sinuses are useful diagnostic procedures for demonstrating the non-spore-forming, thin, gram-positive bacilli that frequently exhibit branching in clinical specimens (Fig. 22.2). Because *Actinomyces* spp. are endogenous biota of the oral cavity, many cases of actinomycosis can be seen in the maxillary region, with draining sinuses in the neck and thorax. Another common site of actinomycosis is the female genital tract, in which the infection is often associated with long standing use of intrauterine devices. Although *Actinomyces israelii* is the most common cause of actinomycosis, other gram-positive anaerobes such

Fig. 22.2 Gram-stained appearance of *Actinomyces israelii*, illustrating the term *Actinomyces*-like ($\times 1000$).

as *Propionibacterium* and *Bifidobacterium* have also been noted to cause this type of infection.

Bacterial vaginosis

Bacterial vaginosis (BV) is thought to arise because of a change in the endogenous microbiota of the vagina. *Lactobacillus* spp. usually constitute the largest portion of the vaginal biota. In BV, a shift in the vaginal biota occurs, resulting in a decrease in the population of lactobacilli and an overgrowth of other endogenous anaerobes of the vagina such as *Mobiluncus* spp., *Bacteroides* spp., *Prevotella* spp., anaerobic gram-positive cocci, and the aerobic bacterium *Gardnerella vaginalis* (see [Chapter 16](#)). Clinical features of BV include a gray-white, homogeneous, malodorous vaginal discharge, with little or no discomfort and no inflammation. BV is associated with an increased risk of acquiring human immunodeficiency virus (HIV) infection and experiencing adverse outcomes in pregnancy and possibly the pathogenesis of pelvic inflammatory disease.

BV is most often diagnosed on clinical appearance and Gram staining of vaginal secretions that reveals the shift in the vaginal biota from predominantly gram-positive lactobacilli to a mixture of *Gardnerella* spp. (gram-variable bacilli) and mixed gram-negative anaerobes. Because many of the anaerobic organisms associated with BV are members of the endogenous microbiota of the female GU tract, culture of vaginal secretions is not performed as part of the diagnosis.

Lactobacillus

Lactobacillus spp. are gram-positive, highly pleomorphic bacilli, which may appear on Gram-stained smears as a coccoid or spiral-shaped organism. There are more than 100 species of *Lactobacillus*. They are considered aerotolerant anaerobes, growing better under anaerobic conditions. Lactobacilli are widely distributed in nature, in foods, and in the normal biota in the human mouth, GI tract, and female genital tract.

Lactobacillus spp. play an important role in the health of the female vaginal tract in that they help protect the host from urogenital infections. Lactobacilli produce lactic acid from glycogen, which lowers the vaginal pH and suppresses the overgrowth of organisms such as *Mobiluncus*, *Prevotella*, and *G. vaginalis*. The *Lactobacillus acidophilus* complex constitutes most of the lactobacilli of the healthy vagina, but *L. fermentum*, *L. vaginalis*, *L. salivarius*, *L. plantarum*, and other species have also been recovered.

Lactobacillus spp. can often be recovered from urine and genital cultures, in which their role in the infectious process is doubtful. Systemic human infections are rare and are associated with the patient's endogenous organisms, typically originating from the oral cavity. Serious infections, primarily bacteremia and endocarditis, are known to occur in immunocompromised patients. Endocarditis is the most common clinical disease caused by lactobacilli and has a high mortality rate (23% to 27%). *Lactobacillus rhamnosus* is the species most often associated with septicemia and endocarditis. Other infections associated with lactobacilli include intraabdominal abscesses, meningitis, oral infections, and conjunctivitis. Opportunistic infections such as endocarditis and polymicrobial abscesses caused by lactobacilli are sometimes seen in patients who previously received the antimicrobial agent vancomycin. Although vancomycin is normally effective in treating infections caused by almost all gram-positive bacteria, many lactobacilli are resistant to the agent and consequently will be able to overgrow other inhibited gram-positive organisms during

vancomycin therapy. In addition to vancomycin, lactobacilli are frequently resistant to the cephalosporins. Once the organism is confirmed as clinically significant and not a contaminant, treatment is usually with penicillin with an aminoglycoside.

Anaerobic gram-negative bacilli

Gram-negative anaerobic bacilli are all non-spore-forming organisms and are often found as members of the endogenous microbiota. They can be found as part of the microbiota of the oral cavity and GI and GU tracts. The bacilli most commonly encountered in clinical specimens include members of the *B. fragilis* group and the genera *Porphyromonas*, *Prevotella*, and *Fusobacterium*.

Clinical infections

Anaerobic gram-negative bacilli are frequently found in mixed infections such as abscesses occurring beneath mucosal surfaces. As predominant members of the GI biota, the organisms are often associated with peritoneal infections following disruption of the GI tract lining. Members of the *B. fragilis* group are the most commonly isolated anaerobes from blood cultures. These agents are more virulent and antimicrobial resistant than many other anaerobic bacteria. *B. fragilis* is the anaerobic species most commonly isolated from blood, ulcers, intraabdominal abscesses, and several other specimens.

Brain abscesses are frequently caused by anaerobic organisms such as *Prevotella*, *Porphyromonas*, and *Fusobacterium* found as endogenous microbiota of the oral cavity. Brain abscesses are often the result of complications from sinusitis, otitis media, and dental infections. The anaerobic gram-negative bacilli are often associated with mixed biota in diabetic foot ulcers and decubitus pressure sores. It is often difficult to determine whether the organisms recovered in culture from these specimens are pathogens or merely colonizers. Lemierre disease, a syndrome of thrombophlebitis of the jugular vein that occurs rarely following group A streptococcal pharyngitis, is caused by *F. necrophorum*. The streptococcal infection produces a peritonsillar abscess containing a number of bacterial species. The abscess aids *F. necrophorum* in penetrating the tissue to reach the jugular veins. *Bilophila wadsworthia* is a human pathogen associated with polymicrobial intraabdominal abscesses and gangrenous appendicitis in children. The bile-resistant *Alistipes* species *A. finegoldii*, *A. onderdonkii*, and *A. shahii* are linked to appendicitis in children and adults and intraabdominal abscesses.

Anaerobic cocci

Most of the anaerobic gram-positive cocci were classified previously in the genus *Peptostreptococcus*, with the exception of *Peptococcus niger*, an infrequent isolate. However, the genus *Peptostreptococcus* has been reclassified into at least six different genera: *Peptostreptococcus*, *Anaerococcus*, *Finegoldia*, *Gallicola*, *Parvimonas*, and *Peptoniphilus*. Taxonomy of this group is still in a state of flux, with new genera being added, so this chapter will continue to use the term *peptostreptococci* or *anaerobic gram-positive cocci* when discussing these organisms as a group.

Although several genera of anaerobic gram-negative anaerobic cocci are found in the endogenous microbiota, only

Veillonella spp. are implicated as pathogens. *Veillonella* are very small (0.3–0.5 µm in diameter) and inhabit the oral cavity. They are usually seen in mixed biota abscesses.

Clinical infections

The anaerobic cocci are weakly pathogenic but can be isolated from a wide variety of infections, including brain abscess, aspiration pneumonia, lung abscess, and gingivitis and other periodontal diseases. They are usually associated with polymicrobial infections but can occasionally be recovered from blood cultures and can cause infections following orthopedic surgery. *Finnegoldia magna* is the most pathogenic of the anaerobic cocci and the one most often isolated in pure culture, including cases of endocarditis, meningitis, and pneumonia. *Peptostreptococcus anaerobius* is linked to polymicrobial abscesses of the brain, ear, jaw, pleural cavity, and other sites. Additional important species include *Peptoniphilus asaccharolyticus*, *Peptoniphilus indolicus*, *Peptoniphilus harei*, *Parvimonas micra*, *Anaerococcus vaginalis*, and *Anaerococcus prevotii*. Evaluating the significance of the anaerobic gram-positive cocci isolated in clinical specimens is often difficult.

Specimen selection, collection, transport, and processing

Specimen quality

When health care providers suspect an infection involving anaerobes, the specimen collected must be from the actual site of the infection and not just a swab of a mucosal surface. It must also be collected in a manner that avoids prolonged exposure to oxygen and must be transported as quickly as possible to the laboratory under anaerobic conditions. The laboratory plays an important preanalytic role in specimen selection by providing guidelines for specimen collection and by ensuring that a suitable anaerobic transport system is available.

As noted, most anaerobic infections are caused by members of the endogenous microbiota. An improperly collected specimen may result in the growth of many different anaerobes, making the interpretation of culture results difficult. The consequences of working up improper or incorrectly collected or transported specimens places a burden on the laboratory and may provide the health care provider misleading results. Consequently, the laboratory, with the cooperation of the medical staff, must develop criteria for the rejection of inappropriate specimens. Specimens likely to contain anaerobic bacteria as normal microbiota are inappropriate for anaerobic culture. Specimens that are acceptable for anaerobic culture are listed in Table 22.6. Conversely, Box 22.3 lists specimens not recommended for anaerobic culture. All of these specimens are likely to result in the growth of many different anaerobes that are colonizing the mucosal surface at the site of specimen collection, making it difficult to determine which, if any, are causing infection.

Specimen transport and processing

Regardless of the type of specimen submitted for anaerobic bacteriology, it must be transported and processed as

Table 22.6 Acceptable specimens for anaerobic bacteriology

Anatomic source	Specimens and recommended methods of collection
Central nervous system	Cerebrospinal fluid, aspirated abscess material, tissue from biopsy or autopsy
Dental, ear-nose-throat specimens	Aspirated abscess material, e.g., nasal sinus; biopsied tissue
Localized abscesses	Needle and syringe aspiration of closed abscesses
Decubitus ulcers	Aspirated pus
Sinus tracts or draining wounds	Aspirated material
Deep tissue or bone	Specimens obtained during surgery from depths of wound or underlying bone lesion
Pulmonary	Aspirate obtained by direct lung puncture, transtracheal aspirate, pleural fluid obtained by thoracentesis, open lung biopsy, sulfur granules from draining fistula
Intraabdominal	Aspirate from abscess, ascites fluid, peritoneal fluid, tissue
Urinary tract	Suprapubic bladder aspiration, cystoscopic urine
Female genital tract	Aspirate from loculated abscess; culdocentesis fluid aspirate, fallopian tube fluid or tissue, IUD for actinomycosis, placenta tissue
Other	Blood, bone marrow, synovial fluid, biopsied tissue from any normally sterile site

IUD, Intrauterine device.

Modified from Engelkirk, P. G., et al. (1992). *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.

BOX 22.3 Unacceptable specimens for anaerobic bacteriology^a

- Throat swabs, nasopharyngeal swabs; sputum obtained by nasotracheal or endotracheal suction; bronchial washings or other specimens obtained via a bronchoscope (unless a protected double-lumen catheter is used); expectorated sputum
- Gingival swabs or any other intraoral surface swabs
- Large bowel contents^b; feces^b; ileostomy and colostomy effluents; rectal swabs; gastric and small bowel contents
- Voided or catheterized urine
- Vaginal, cervical, or urethral swabs; female genital tract specimens collected via the vagina^c; swabs of a vaginal discharge
- Surface swabs from decubitus ulcers, perirectal abscesses, foot ulcers, exposed wounds, eschars, pilonidal sinuses, and other sinus tracts
- Any material adjacent to a mucous membrane that has not been adequately decontaminated

^aAll would contain endogenous anaerobic microbiota.

^bExcept for *Clostridioides difficile*, *Clostridium botulinum*, and other specific causative agents.

^cExcept for suction curettages or other specimens collected via a double-lumen catheter.

rapidly as possible and with minimum exposure to oxygen. Specimens are usually collected from a warm, moist environment that is low in oxygen. It is important to avoid shocking the anaerobes by exposing them to oxygen or permitting them to dry out. In addition, the specimens should not be refrigerated, and the amount of time they remain at room temperature should be minimized.

Aspirates

Abscess specimens collected by needle and syringe are better for anaerobic bacteriology than those collected by swab because they are less likely to be contaminated by endogenous microbiota present at the mucosal or skin surface; also, swabs collect less material. The aspirate should be injected into an oxygen-free transport tube or vial containing a prereduced, anaerobically sterilized (PRAS) transport medium, such as the one shown in Fig. 22.3. PRAS media (Anaerobe Systems, Morgan Hill, CA) are prepared by boiling (to remove dissolved oxygen), autoclaving (to sterilize the mixture), and replacing any air with an oxygen-free gas mixture. For serosanguinous fluids that might clot, the anticoagulant EDTA should be used.

Once in the laboratory, aspirates in transport containers should be vortexed to ensure even distribution of the material, especially when the sample is grossly purulent. Using a sterile Pasteur pipette, one drop of purulent material or two to three drops of nonpurulent material should be added to each plate and streaked to obtain well-isolated colonies. A few drops of the specimen may also be inoculated into the bottom of a tube of enriched thioglycollate or cooked meat broth. Finally, one drop of material is spread evenly over an alcohol-cleaned glass slide for Gram staining. The slide should be air-dried and fixed with methanol, not heat-fixed.

Swabs

Swabs, in general, are not appropriate for anaerobic culture. They should be used only when aspiration of material is not possible and a biopsy specimen is not available. When swabs are deemed necessary, they should always be transported under anaerobic conditions. A number of swab transport systems suitable for anaerobes are commercially available.

On arrival in the laboratory, the swab should be placed into a tube containing about 0.5 mL of sterile thioglycollate broth. The swab is vortexed vigorously to remove the clinical material from the swab and then pressed firmly against the inner wall of the tube to remove as much liquid as possible. The remaining liquid suspension is used to inoculate media, as described earlier for an aspirate. Alternatively, the ESwab transport system (COPAN Diagnostics, Murrieta, CA; see Fig. 22.3), which

contains a swab transported in 1 mL of a prereduced liquid Amies medium that can maintain aerobic and anaerobic organisms for up to 48 hours at room temperature can be used.

Tissue

Tissue specimens collected by biopsy or at autopsy from usually sterile sites are acceptable specimens for anaerobic culture. Small pieces of tissue can be placed in anaerobic transport tubes or vials containing PRAS medium to keep the tissue moist. When inserting swabs or small pieces of tissue into an anaerobic transport container, care must be taken not to tip the container. This would cause the heavier than air, oxygen-free gas mixture to be displaced by room air, thus defeating the primary purpose of using such a transport medium.

Larger tissues of more than 1 cm² can maintain a reduced atmosphere as long as the transport time to the laboratory is minimized. These specimens can be sent in a sterile container with sterile, wet gauze. If a delay in transport is expected, tissue may be transported in pouches containing an oxygen-free atmosphere. These bags or pouches are available commercially from Becton-Dickinson Diagnostic Systems (Sparks, MD; GasPak pouches), Mitsubishi Gas Chemical America (New York, NY; AnaeroPack system), and other companies. These containers are described in more detail later (see the “Anaerobic Incubation of Inoculated Media” section). To process the tissue or bone fragments in the laboratory, 1 mL of sterile thioglycollate broth is added to a sterile tissue grinder. The piece of tissue or bone fragment is homogenized until a thick suspension is obtained. Ideally, this procedure is performed in an **anaerobic chamber**. If a chamber is not available, the grinding must be accomplished as quickly as possible in a biological safety cabinet. The suspension is used to inoculate media, as described earlier for an aspirate.

Blood

Blood must be cultured to recover any bacteria or yeasts that might be present. This usually requires aseptic inoculation of anaerobic and aerobic blood culture bottles. At least one anaerobic blood culture bottle should be used. Once inoculated, bottles should be rapidly transported to the laboratory, where they are incubated at 35° to 37° C. Blood for culture must be carefully collected to minimize contamination with skin biota. This usually is accomplished by meticulous preparation of the venipuncture site with a bactericidal agent, such as tincture of iodine, iodophor, or chlorhexidine gluconate in combination with 70% isopropyl alcohol. Blood culture collection is covered in more detail in Chapter 36.

Processing clinical samples for recovery of anaerobic pathogens

To ensure that results of anaerobic cultures are clinically significant, only properly selected, collected, and transported specimens should be processed. Ideally, once a specimen arrives in the laboratory, it should be placed immediately into an anaerobic chamber to prevent further exposure to oxygen. Anaerobic chambers allow all steps in the processing of a specimen to be performed in an oxygen-free environment. In laboratories not equipped with anaerobic chambers, holding

Fig. 22.3 Anaerobic specimen collection and transport systems. *Left*, BBL Port-A-Cul with prereduced gel. *Right*, ESwab with prereduced liquid Amies medium. (BBL Port-A-Cul courtesy BD Diagnostic Systems, Sparks, MD; ESwab courtesy COPAN Diagnostics, Murrieta, CA.)

systems may be used (see the “Inoculation Procedures” section later in this chapter). To comply with mandatory infectious disease safety policies, laboratory scientists must follow appropriate safety precautions. Disposable gloves should be worn and a biosafety cabinet used when handling clinical specimens containing potentially infectious agents. The following procedures should be performed on clinical specimens for the recovery of anaerobic bacteria:

- Macroscopic examination of the specimen
- Preparation of Gram-stained smears for microscopic examination
- Inoculation of appropriately plated and tubed media, including media specifically designed for culturing anaerobes
- Anaerobic incubation of inoculated media

Macroscopic examination of specimens

Each specimen received in the anaerobic bacteriology section should be examined macroscopically and pertinent observations recorded. Some characteristics to note during the macroscopic examination are listed in [Table 22.7](#).

Direct microscopic examination of specimens

Direct smears for Gram stain should be prepared on all specimens received for anaerobic culture for the following reasons:

- The Gram-stained smear reveals the various morphotypes and relative number of microorganisms present in the specimen. The presence of multiple distinct morphologic forms suggests that a polymicrobial infectious process is present.
- Certain morphotypes might provide a presumptive identification of organisms and serve as a guide to media selection. If large, gram-positive bacilli suggestive of clostridia are seen, especially in cases of myonecrosis, the laboratory may want to inoculate an egg yolk agar (EYA) plate to detect lecithinase or lipase activity in addition to the media normally inoculated. Thin,

gram-negative bacilli with tapered ends are suggestive of *Fusobacterium nucleatum*, whereas extremely pleomorphic, gram-negative bacilli with bizarre shapes are suggestive of *Fusobacterium mortiferum* or *F. necrophorum*. Gram-negative coccobacilli may be *Bacteroides*, *Porphyromonas*, or *Prevotella*. The presence of gram-negative coccobacilli with gram-negative fusiforms along with many polymorphonuclear white blood cells in a sputum sample might indicate aspiration pneumonia.

- The Gram-stained smear often reveals the presence of leukocytes, indicating an inflammatory response at the site of the infection. However, certain anaerobes produce necrotizing toxins (leukocidins) that destroy leukocytes. Thus the absence of leukocytes in a Gram-stained smear can never rule out the involvement of anaerobes.
- The Gram-stained smear may also reveal the presence of squamous epithelial cells that would suggest mucosal surface contamination during specimen collection. Such a specimen would likely not provide useful information to the clinician. The laboratory should be cautious in processing such a specimen.
- Finally, the Gram-stained smear can serve as a valuable quality control tool. Failure to isolate certain organisms observed in the direct Gram-stained smear might indicate that problems exist with the anaerobic culture procedure being used. Failure to recover certain morphotypes might be the result of oxygen exposure during specimen collection and transport or because the patient received antimicrobial agents that inhibited growth of the organisms on the plated media.

It is recommended that direct smears for Gram stain be methanol-fixed rather than heat-fixed. Methanol fixation preserves the morphology of leukocytes and bacteria better than heat fixation. Gram-negative anaerobes frequently stain a pale pink when safranin is used as the counterstain and thus may be overlooked in Gram-stained smears of clinical specimens and blood cultures. To enhance the red color of gram-negative anaerobes, the use of 0.1% basic fuchsin as the counterstain or extension of the counterstaining with safranin for 3 to 5 minutes is recommended.

Table 22.7 Characteristics to note during the macroscopic examination of a specimen for anaerobic culture

Questions to ask	Comments
Is it an appropriate specimen?	Inappropriate specimens should be rejected
Was it submitted in an appropriate transport container or medium?	Improperly transported specimens should be rejected
Does the specimen have a foul odor?	Many anaerobes, especially <i>Fusobacterium</i> and <i>Porphyromonas</i> , have foul-smelling metabolic end products
Does the specimen fluoresce brick red when exposed to long-wave (366-nm) ultraviolet light?	Pigmented species of <i>Porphyromonas</i> and <i>Prevotella</i> produce substances that fluoresce under long-wave ultraviolet light before becoming darkly pigmented. Although a brick red fluorescence is presumptive evidence of these organisms, some members of this group fluoresce colors other than brick red
Is the tissue necrotic or exudate black?	Such discoloration may be caused by the pigment produced by pigmented species of <i>Porphyromonas</i> and <i>Prevotella</i>
Does the specimen contain sulfur granules?	Such granules are associated with actinomycosis, a condition caused by <i>Actinomyces</i> , <i>Pseudopropionibacterium propionicum</i> , and closely related organisms, such as <i>Cutibacterium acnes</i> .

Modified from Engelkirk, P. G., et al. (1992). *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.

Inoculation of appropriate plated and tubed media

The choice of media for use in the anaerobic bacteriology laboratory is an extremely important aspect of successful anaerobic bacteriology. Anaerobes are fastidious and have special nutritional requirements. Media for obligate anaerobes should contain horse or sheep red blood cells and be supplemented with vitamin K, hemin, and yeast extract. No one medium is likely to support the growth of all anaerobic bacteria; however, CDC blood agar provides the best recovery.

Primary plating media for anaerobic cultures

Table 22.8 lists the primary media recommended for the recovery of anaerobes. Although these media are designed for anaerobes, they also support the growth of most aerobes, so selective media are useful to inhibit facultative anaerobes. At a minimum, specimens for anaerobic culture should be plated onto a nonselective blood agar (e.g., Brucella agar or CDC blood agar), a biplate containing *Bacteroides bile esculin*

(BBE), and kanamycin and vancomycin with laked sheep blood (KVLB) agars. Laked blood is red blood cells lysed through a series of freeze-thaw cycles. Many laboratories also inoculate specimens onto a phenylethyl alcohol (PEA) or colistin–nalidixic acid (CNA) blood agar plate. Either of these media will inhibit facultative anaerobic gram-negative bacteria that can overgrow anaerobes present in the specimen. Surgical specimens or sterile site specimens should also be inoculated into an anaerobic broth medium such as thioglycollate or prereduced chopped meat to serve as a backup source of culture material. If the primary plates do not recover anaerobes, the broth should be subcultured to anaerobic plates. The broth should be held for up to 14 days.

The ideal media for use in the culture of anaerobes are those that have never been exposed to oxygen or have been exposed only briefly. Media should be at room temperature and prereduced when inoculated. Media exposed to air for extended periods may contain toxic substances, produced

Table 22.8 Primary setup media recommended for recovery of anaerobes^a

Medium	Organisms	Comments
Anaerobic blood agar (e.g., CDC medium)	Supports growth of almost all obligate and facultative anaerobes, best for anaerobic gram-positive cocci	An enriched medium containing horse or sheep red blood cells for enrichment and detection of hemolysis, hemin, vitamin K (required by some <i>Porphyromonas</i> spp.), and yeast extract
<i>Bacteroides bile esculin</i> agar	Supports growth of bile-tolerant <i>Bacteroides</i> spp., some strains of <i>Fusobacterium mortiferum</i> , <i>Klebsiella pneumoniae</i> , enterococci, and yeasts may grow to a limited extent	A selective medium containing gentamicin (which inhibits most aerobic organisms), 20% bile (which inhibits most anaerobes), and esculin; used primarily for rapid isolation and presumptive identification of members of the <i>B. fragilis</i> group, which grow well on <i>Bacteroides bile esculin</i> agar (because of their bile tolerance) and turn the originally light-yellow medium to black (because of esculin hydrolysis)
Brucella blood agar	Supports growth of almost all obligate and facultative anaerobes, best for gram-negative bacteria	An enriched medium containing sheep red blood cells for enrichment and detection of hemolysis, casein peptones, dextrose, yeast extract, vitamin K, and hemin
Kanamycin–vancomycin–laked blood agar	Supports growth of <i>Bacteroides</i> and <i>Prevotella</i> spp.; yeasts and kanamycin-resistant, facultative, gram-negative bacilli will also grow	A selective medium containing kanamycin (which inhibits most facultative gram-negative bacilli), vancomycin (which inhibits most gram-positive organisms and vancomycin-sensitive strains of <i>Porphyromonas</i> spp.), and laked blood (which accelerates production of brown-black pigmented colonies by certain <i>Prevotella</i> spp.); used primarily for rapid isolation and presumptive identification of pigmented species of <i>Prevotella</i>
Phenylethyl alcohol agar	Supports growth of almost all obligate anaerobes (gram-positive and gram-negative) and gram-positive, facultative anaerobes	A selective medium containing sheep red blood cells and phenylethyl alcohol; used primarily to suppress the growth of any facultative, gram-negative bacilli (e.g., Enterobacterales) that might be present in the clinical specimen, especially swarming <i>Proteus</i> spp.
Colistin–nalidixic acid blood agar plate	Supports growth of almost all obligate anaerobes (gram-positive and gram-negative) and gram-positive, facultative anaerobes	A selective medium containing sheep red blood cells and the antimicrobials colistin and nalidixic acid; used primarily to suppress the growth of any facultative, gram-negative bacilli (e.g., Enterobacterales) that might be present in the clinical specimen, especially swarming <i>Proteus</i> spp.
Anaerobic broth (e.g., thioglycollate and chopped or cooked meat)	Supports growth of almost all types of bacteria; in thioglycollate broth, obligate aerobes and microaerophiles grow near the top, obligate anaerobes at the bottom, and facultative anaerobes throughout the broth	Because obligate anaerobes can be overgrown by more rapidly growing facultative organisms present in the specimen and killed by their toxic, metabolic by-products, thioglycollate broth serves only as a backup source of culture material (e.g., in case there is no growth on plated media because of a jar failure or presence of antimicrobial agents in the specimen); broth cultures should never be relied on exclusively for isolating anaerobes from clinical material

^aNot all media listed are needed for every culture. Each laboratory needs to decide which media are appropriate depending on specimen source and pathogens expected. At a minimum, each culture should include an enriched anaerobic blood agar plate, *Bacteroides bile esculin* agar plate, kanamycin–vancomycin–laked blood agar plate, and an anaerobic broth.

as a result of the reduction of molecular oxygen. Such media may also have redox potentials above those required for anaerobes to grow. To provide the best recovery of anaerobes, fresh plated media should be stored in an anaerobic chamber or holding system until used. An alternative is to use commercial media, such as PRAS media, that have been prepared, packaged, shipped, and stored under anaerobic conditions. With the PRAS media shown in Fig. 22.4, growth is initiated quickly. Many anaerobes produce sufficient growth after only 24 hours of incubation. Studies have demonstrated that PRAS media perform better than other commercially available media.

Media for aerobic incubation

In most cases, a request for anaerobic culture on a specimen is also accompanied by a request for aerobic culture. In addition to the battery of selective anaerobic media to be incubated anaerobically, a variety of plated media to be incubated in room air and in a CO₂ incubator are also inoculated. The specific media differ somewhat among laboratories and will depend on the specimen type; nevertheless, 5% sheep blood, MacConkey, and chocolate agar plates are usually included. Some laboratories also routinely include a CNA blood agar plate to select for gram-positive bacteria. Fig. 22.5 shows a typical plating protocol for a wound sample and the types of results that might be expected.

Inoculation procedures

In laboratories not equipped with an anaerobic chamber, inoculation of appropriate plated and tubed media could be performed in an area with a suitable nitrogen gas holding system. Such a holding system, which may use a jar, box, or other small chamber, allows plates that have not been inoculated to be held under anaerobic conditions until needed. Inoculated plates should be held under near-anaerobic conditions until placed into an anaerobic jar or bag. Care should be taken to ensure that inoculated plates do not remain in the holding jar at room temperature for extended periods (not

Fig. 22.5 Culture results that might be obtained from the primary isolation of a hypothetical wound specimen. Shown are the media and atmospheric conditions that would support the growth of various organisms contained in the specimen. BBE, Bacteroides bile esculin agar; BRU/BA, Brucella blood agar; CHOC, chocolate agar; CNA, colistin–nalidixic acid blood agar; KVLB, kanamycin–vancomycin–laked blood agar; MAC, MacConkey agar; PEA, phenylethyl alcohol blood agar; SBA, sheep blood agar. (From Engelkirk, P. G., et al. [1992]. *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.)

longer than 1 hour). Also, so that the holding jar can maintain as low an oxygen concentration as possible, care should be taken to minimize convection currents whenever freshly inoculated plates are added to the jar. A good quality control procedure to ensure that the agar is maintained under proper conditions is to inoculate an agar plate with *F. nucleatum* and place the plate in the holding jar. After all of the specimens have been inoculated, the agar plate can be incubated anaerobically. Growth of *F. nucleatum* indicates that the agar was maintained under near-anaerobic conditions.

Some microbiologists believe that it is better to batch-process specimens than to process each specimen as it arrives in the laboratory. This relieves the concern that freshly inoculated plates will remain at room temperature in a holding system that may contain some oxygen. Batch processing is an acceptable alternative for aspirates and specimens received in proper transport containers—those kept moist under anaerobic conditions. It would be unacceptable, however, to batch-process improperly submitted specimens (e.g., dry swabs) or clinical specimens apt to contain rapidly growing bacteria. The delay would further expose anaerobes to

molecular oxygen, increase the likelihood of specimens drying out, and decrease the probability of recovering anaerobes.

Anaerobic incubation of inoculated media

After specimens have been processed and inoculated onto the appropriate media, the inoculated plates must be incubated anaerobically at 35° to 37° C. The most common and practical choices for anaerobic incubation systems for clinical laboratories are anaerobic chambers, anaerobic jars, and anaerobic bags or pouches. The choice of system is influenced by a number of factors, including financial considerations, the number of anaerobic cultures performed, and space limitations.

An alternative method is the OxyPlate (Oxyrase, Mansfield, OH), which contains the proprietary substance Oxyrase. This reducing agent protects obligate anaerobes growing on the agar surface. After inoculation, the plate is put into an OxyDish, producing a self-contained environment for growing anaerobes in an ambient air incubator. This system eliminates the use of anaerobic chambers and gas packs.

Anaerobic chambers

The ideal anaerobic incubation system is an anaerobic chamber, which provides an oxygen-free environment for inoculating media and incubating cultures. Identification and susceptibility tests also can be performed in the chamber. Anaerobic chambers are available as sealed glove boxes and gloveless chambers. Glove boxes are fitted with airtight rubber gloves (Fig. 22.6). They are easier to use and less susceptible to oxygen contamination than gloveless chambers. Glove boxes also use less gas and are therefore cheaper to operate. The microbiologist inserts his or her hands into the gloves and manipulates specimens, plates, and tubes inside the chamber. However, they have the disadvantage of trying to accommodate many different hand sizes into one pair of gloves. This disadvantage can be overcome by the use of the gloveless anaerobic chamber (Fig. 22.7). Airtight rubber sleeves that fit snugly against the user's bare forearms are used in place of gloves, enabling the microbiologist to work within

an anaerobic environment with bare hands. However, the cuffs for the arms might not accommodate everyone, allowing air to leak around the arms of smaller individuals. It is recommended that disposable gloves be worn if clinical specimens are being processed in gloveless chambers. Subsequent manipulation of cultures may be performed with bare hands, if preferred. Some gloveless models also have a dissecting microscope mounted on the front of the rigid Plexiglas chamber. This enables the user to observe colony morphology within the chamber, eliminating the need to remove the plates from the chamber, which would result in exposure of the colonies to oxygen.

Anaerobic chambers contain a catalyst, a desiccant, anaerobic gas (5% H₂, 5% to 10% CO₂, and 85% to 90% nitrogen), and an oxidation-reduction indicator. The catalyst, usually palladium-coated alumina pellets, removes residual oxygen from the atmosphere in the chamber. With time, the catalyst pellets become inactivated by water and gaseous metabolic end products produced by the anaerobes, particularly hydrogen sulfide (H₂S). This by-product of metabolism not only "poisons" the catalyst but can harm the chamber's electronics. A product called Anotox (Anaerobe Systems, Morgan Hill, CA) has been shown to absorb these metabolites and prolong catalyst life.

Silica gel is sometimes used as a desiccant to absorb the water formed when H₂ combines with free oxygen in the presence of the catalyst and from water vapor from the bacterial media. Unfortunately, the gel can be overwhelmed and become saturated without the users knowing. Desiccants that change color when saturated are not recommended because of the fine powder they contain that can circulate throughout the chamber. A better, albeit more expensive, method is to use a solid-state dehumidifier.

Carbon dioxide is required for the growth of many anaerobic organisms, and inert nitrogen gas is used as filler for the remaining percentage of the anaerobic atmosphere.

Fig. 22.6 Glove box type of anaerobic chamber. The flexible, clear vinyl chambers are available in three lengths—36, 59, and 78 inches—including one fitted with two pairs of gloves so two microbiologists can use the chamber simultaneously. (Courtesy Coy Laboratory Products, Grass Lake, MI.)

Fig. 22.7 Gloveless type of anaerobic chamber with dissecting microscope attachment. This stainless steel and Plexiglas chamber is manufactured by Anaerobe Systems. (Courtesy Anaerobe Systems, Morgan Hill, CA; Sheldon Manufacturing, Cornelius, OR.)

Anaerobic gas is one of the biggest expenditures in operating an anaerobic chamber. Using high-quality anaerobic gas (calibrated or certified) substantially increases the cost. Most anaerobe chambers can operate with lower-quality gas. Small amounts of oxygen in these gases can generally be removed by the anaerobic chamber.

The College of American Pathologists requires that laboratories performing anaerobic cultures verify daily that anaerobiosis is achieved. This requires the use of an oxygen reduction indicator, which can be methylene blue or resazurin. Methylene blue remains white in the absence of oxygen (reduced) and turns blue in the presence of oxygen; resazurin goes from colorless in the absence of oxygen to pink in the presence of oxygen. These agents can be purchased as strips inside foil pouches and opened inside the chamber or ampules that can be broken to expose the reagent to air just before anaerobic inoculation. A problem with this method is that the agents change color at too high a level of oxygen concentration, which can make it difficult to react in time to maintain the viability of strict anaerobes. Digital oxygen indicators are available that offer faster response times to changes in atmospheric concentrations.

Anaerobic jars

For small laboratories, in which the volume of anaerobic cultures may not justify the purchase of anaerobic chambers, alternative systems are available. One option is the GasPak jar (BD Diagnostic Systems; Fig. 22.8). These jars have been used in clinical laboratories for many years, enabling even small laboratories to perform satisfactory anaerobic bacteriology. Some models accommodate a larger number of plates and microtiter susceptibility trays and anaerobic identification strips or trays. Other anaerobic jars or containers are available from other companies. None of these systems provide all the features or advantages of anaerobic chambers, and cost analysis reveals that over time, a chamber is actually more cost-effective.

Anaerobic jar systems use an envelope gas generator. Numerous gas-generating systems are available and can be divided into newer systems that are waterless and older systems that require water. When water is added to the GasPak

Fig. 22.8 Anaerobic jars. This photograph depicts two of the many different types of anaerobic jars available commercially. As can be seen, the jars can also be used to culture microaerophilic organisms (CampyPak Plus). (Courtesy BD Diagnostic Systems, Sparks, MD.)

envelope, two gases are generated, CO_2 and H_2 . The two gases have a function similar to that in the anaerobic chamber, with H_2 combining with oxygen to form water. Hydrogen is explosive, and if the catalyst is not functioning properly, hydrogen gas will accumulate in the jar. An individual should never open the jar in the vicinity of an open flame. A methylene blue oxidation-reduction indicator strip is always added to the jar to verify that an anaerobic atmosphere was achieved. It takes about 30 to 45 minutes to obtain an anaerobic environment. However, it may take several hours for the methylene blue indicator to change from blue to white. If the catalyst performs properly, water vapor will be present on the inside of the jar, and the indicator strip will be white. Some of the newer gas-generating packets contain a built-in indicator.

Failure to achieve anaerobic conditions could be the result of a “poisoned catalyst” or a crack in the jar, lid, or O-ring. A poisoned catalyst results from the gases, particularly H_2S , produced by anaerobes. The reusable catalyst pellets can be rejuvenated after every use by heating in a 160°C oven for a minimum of 2 hours. The waterless, gas-generating systems (AnaeroPack system, Mitsubishi Gas Chemical America, New York, NY; BD GasPak EZ anaerobe pouch system, BD Diagnostics) are single-use disposable packets designed to produce anaerobic conditions without the use of water or a catalyst. Once the packet has been removed from its foil container, it must be rapidly (within 1 minute) placed in the anaerobe jar or bag. The atmospheric oxygen in the container is quickly absorbed, with the simultaneous generation of CO_2 . The reaction proceeds without the generation of H_2 , so it eliminates the need for a catalyst. No water is produced in response to the anaerobic atmosphere generation, so plates in bags can be more easily viewed. Another alternative is the Anoxomat (Advanced Instruments, Norwood, MA), which is a gas evacuation system that creates an anaerobic environment within 3 minutes (Fig. 22.9).

Fig. 22.9 Advanced Anoxomat Mark II system (Advanced Instruments, Norwood, MA) is a gas evacuation replacement system. (Courtesy Dr. Steven Dallas, University of Texas Health Science Center, San Antonio, TX.)

The major disadvantage of any anaerobic jar system is that the plates must be removed from the jar to be examined and processed. This exposes the bacteria to oxygen, which is especially harmful to the anaerobes during their first 48 hours of growth. For this reason, a suitable holding system should ideally be used in conjunction with anaerobic jars. Plates can be removed from the anaerobic jar, placed in an oxygen-free holding system, removed one by one for rapid examination of colonies, and then quickly returned to the holding system. Plates never should remain in room air on the open bench.

Anaerobic bags

An alternative to an anaerobic chamber or jars are anaerobic bags or pouches (Fig. 22.10). These are available from BD Diagnostic Systems, Mitsubishi, Oxoid (Basingstoke, United Kingdom), Hardy Diagnostics (Santa Monica, CA), and other

Fig. 22.10 Anaerobic pouch. This photograph depicts the GasPak pouch, one of the commercially available anaerobic bag or pouch systems. Identification and susceptibility testing systems requiring anaerobic incubation can be incubated in some bags or pouches. (Courtesy BD Diagnostic Systems, Sparks, MD.)

manufacturers. One or two inoculated plates are placed into a bag, an oxygen removal system is activated, and the bag is sealed and incubated. Theoretically, the plates can be examined for growth without removal of the plates from the bags, so the colonies are not exposed to oxygen. However, with some of the products, a water vapor film on the inner surface of the bag or the lid of the plate can sometimes obscure vision. In such cases, the plates must be removed from the bag to observe them for growth, and a new bag and oxygen removal system must be used whenever additional incubation is required. As with the anaerobic jar, plates must be removed from the bags to work with the colonies at the bench. An anaerobic holding system should therefore be used in conjunction with any of the anaerobic bags.

Any of these bags are also useful transport devices. For example, a biopsy specimen can first be placed into a sterile screw-capped tube containing sterile saline, which is then placed in one of these bags. Once the oxygen removal system has been activated, the specimen is transported to the laboratory in the bag, thereby minimizing exposure to oxygen. This is especially important if delays in transport of the specimen are expected.

Procedures for identifying anaerobic isolates

Various methods are available to clinical microbiologists for identifying anaerobic isolates (Table 22.9). The method and level of identification usually depend on the size and capabilities of the laboratory and whether the organism is from a mixed infection or from a sterile site such as blood or another sterile body fluid (e.g., synovial, peritoneal, or pleural fluid). Presumptive identifications of microorganisms have become more popular in recent years primarily because of increased emphasis on speed and cost reduction. Several anaerobic bacteria can be identified in the laboratory using presumptive identification criteria, thereby providing physicians with timely information concerning the presence of anaerobes in

Table 22.9 Options available for identifying anaerobic bacteria		
Identification technique	Time to obtain results	Extent of identification
Presumptive identification—based on colony morphology, Gram stain observations, and results of simple tests (e.g., disks, catalase, spot indole)	Same day that PC-SC plate is available	Limited capability; many clinically encountered anaerobes cannot be identified
Definitive identification—commercially available, preexisting, enzyme-based identification systems (e.g., ANIDENT, RapID ANA-II, BBL Crystal, Vitek ANI card)	Same day that PC-SC plate is available (4-hour incubation)	Most commonly encountered, clinically significant anaerobes can be identified
Commercially available biochemical-based identification systems (e.g., API 20A, Minitek)	24–48 hours after PC-SC plate is available	Most commonly encountered saccharolytic anaerobes can be identified, but many asaccharolytic anaerobes cannot be identified
Cellular fatty acid analysis by high-resolution GLC (e.g., MIDI system)	24–48 hours after PC-SC plate is available	Most clinically encountered anaerobes can be identified
16S rDNA sequencing	5 hours after PC-SC plate is available	Most clinically encountered anaerobes can be identified
MALDI-TOF mass spectrometry	Less than 1 hour	Most clinically encountered anaerobes can be identified
GLC, Gas-liquid chromatography; MALDI-TOF, matrix-assisted laser desorption/ionization–time-of-flight; PC-SC, pure culture–subculture; rDNA, ribosomal DNA.		

clinical specimens. The following sections on identification techniques are based on progressively more complex procedures that ultimately can provide the genus and species of an anaerobic bacterium. However, often the most actionable information for the health care provider can be based on the presumptive identification procedures described here, and full identification might not be necessary. Communication with the health care provider is important to determine how far to go with an identification and whether susceptibility testing is required for proper patient management.

The Clinical and Laboratory Standards Institute (CLSI) document (M35-A2, *Abbreviated Identification of Bacteria and Yeast*) provides guidelines for the rapid presumptive identification of commonly encountered anaerobic bacteria. It is an individual laboratory's decision whether such identification will suffice or whether definitive identifications of some isolates are necessary. By using the guidelines in the CLSI document, an isolate can be identified with more than 95% accuracy. Consequently, by combining readily observable colony and Gram stain features with results of simple test procedures, even small laboratories can make presumptive identification of commonly isolated and clinically important anaerobes.

Preliminary procedures

When to examine primary plates

Because many anaerobic infections consist of a mixture of aerobic and anaerobic organisms, the most actionable information that can be provided to the physician is a rapid answer about whether or not the specimen contains anaerobes. The health care provider can then select the most appropriate empiric antimicrobial agents to treat the infection.

Plates incubated in an anaerobic chamber can be examined at any time without exposing the colonies to oxygen. However, those incubated in anaerobic jars, bags, or pouches will be exposed to the potentially damaging effects of oxygen whenever the containers are opened. This may inhibit the growth of strict anaerobes because of the toxic effect of oxygen. If a holding system is available at the anaerobe workstation and is used in conjunction with jars, bags, or pouches, exposure to oxygen will be minimized, and plates can be removed and examined at 24 hours and then placed immediately into the holding system. As soon as all plates have been examined, those requiring additional incubation are returned to an anaerobic system and incubated for an appropriate period before reexamination. If a holding system is not used, inoculated plates should be held until 48 hours before initial examination. Because this delays the time to detection, it certainly is not the optimal method; however, it might be necessary in small laboratories lacking resources. Anaerobic cultures are routinely held for 5 to 7 days to allow growth of particularly slow-growing anaerobes and at least 10 days whenever *Actinomyces* is suspected.

Indications of the presence of anaerobes in cultures

Several clues can alert the clinical microbiologist that anaerobes may be present on the primary plates. These include:

- A foul odor on opening an anaerobic jar or bag. Some anaerobes, especially *C. difficile*, *Fusobacterium*, and *Porphyromonas*, produce foul-smelling metabolic end products that are readily apparent when the jars, bags, or pouches are opened.
- Colonies present on the anaerobically incubated blood agar plates but not on the CO₂-incubated blood or chocolate agar plates
- Good growth (>1 mm in diameter) of gray colonies on a BBE agar plate, characteristic of members of the *B. fragilis* group
- Colonies on KVLB agar or anaerobic blood agar plates that fluoresce brick red under ultraviolet (UV) light or are brown to black in ordinary light, characteristics of pigmented *Porphyromonas* and *Prevotella*. However, most strains of *Porphyromonas* will not grow on KVLB agar because of their sensitivity to vancomycin.
- Double zone of hemolysis on SBA plate incubated anaerobically, suggestive of *C. perfringens*

When anaerobes are suspected, the following steps must be performed and recorded for each colony morphotype present on the anaerobic blood agar plate to initiate presumptive identification of the isolates:

- Describe the colony morphology, and note whether growth occurred on each of the selective (e.g., BBE agar, KVLB agar) and nonselective anaerobic blood agar plates.
- Describe the Gram stain reaction and cell morphology.
- Set up an aerotolerance test (see the "Aerotolerance Testing" section).
- Inoculate a pure culture–subculture plate and add appropriate identification disks.

Colony morphology and Gram stain reaction

The use of a dissecting microscope to observe the fine details of each colony morphotype and pick colonies for isolation is recommended. Fig. 22.11 depicts the appearance of colonies as seen through a dissecting microscope. Growth of a

Fig. 22.11 Anaerobic blood agar plate from an intrauterine device culture as seen through a dissecting microscope. The heavy mixture of sizes and types of colonies makes the task of isolating and identifying colonies very difficult without the enhancement obtained with a dissecting microscope.

Fig. 22.12 Schematic diagram for the initial identification of anaerobic isolates based on Gram-stain morphology. Not all *Clostridium* spp. readily sporulate in clinical specimens or in culture.

particular morphotype can be semiquantitated using terms such as *light*, *moderate*, and *heavy* or a coding system (e.g., 1+, 2+, 3+). The Gram stain reaction and morphologic appearance of the organism aid in the presumptive identification of isolates, as shown in the algorithm in Fig. 22.12.

Aerotolerance testing

The **aerotolerance test** determines whether a microorganism isolated under anaerobic conditions is a strict or facultative anaerobe. Incubating the suspected isolate in aerobic and anaerobic environments determines the atmospheric requirements of the organism. Suspected colonies should be inoculated with a short streak onto a chocolate agar plate for incubation in a CO₂ incubator and an anaerobic blood agar SBA plate incubated anaerobically. By using this technique, many different organisms can be tested for aerotolerance on a single plate. Some laboratories also prefer to inoculate an SBA plate in the same manner to be incubated in an ambient air incubator. This enables differentiation between aerobic and capnophilic organisms.

All aerotolerance test plates should be incubated at 35° C for up to 48 hours. After incubation, the aerotolerance test plates are examined for growth. An obligate anaerobe would grow only on the anaerobically incubated plates. However, some aerotolerant anaerobes (e.g., certain *Clostridium*, *Actinomyces*, *Propionibacterium*, and *Lactobacillus* spp.) can grow on the CO₂-incubated chocolate agar plate, but they usually grow much better on the anaerobically incubated plate. A facultative, non-capnophilic organism will grow on all plates, but a capnophilic aerobe should grow only on the CO₂-incubated chocolate agar plate. *Haemophilus influenzae*, however, will grow on the anaerobic plate and the CO₂-incubated chocolate agar plate but not on the aerobically incubated SBA plate. Table 22.10 describes how the aerotolerance test results are interpreted.

Presumptive identification of clinically significant anaerobes

A presumptive identification of a bacterium is derived from simple colony and Gram stain observations and the results

Table 22.10 Interpretation of aerotolerance test results

	Obligate aerobe	Capnophilic aerobe	Facultative anaerobe	Obligate anaerobe
Blood agar plate incubated aerobically in a non-CO ₂ incubator	+	–	+	–
Chocolate agar plate incubated aerobically in a CO ₂ incubator	+	+	+	–
Blood agar plate incubated anaerobically	–	– ^a	+	+

^a*Haemophilus influenzae* will grow on an anaerobically incubated Brucella blood agar plate but can be differentiated from an anaerobe by its growth on a chocolate agar plate incubated in a CO₂ incubator.

of several relatively rapid and inexpensive tests. The aerotolerance test must be one of the first tests performed. The next section describes tests, some rapid (results in about 1 hour or less), that are of value in presumptively identifying anaerobes commonly encountered in clinical specimens.

Rapid tests

Fluorescence

Many strains of pigmented *Porphyromonas* and *Prevotella* fluoresce brick red under long-wave (366-nm) UV light (Fig. 22.13A). However, some strains fluoresce colors other than brick red (e.g., brilliant red, yellow, orange, pink-orange).

Fig. 22.13 Examples of fluorescence observed with long-wave ultraviolet light. **A**, Brick red fluorescence observed with *Porphyromonas asaccharolytica*. **B**, Chartreuse fluorescence of *Fusobacterium nucleatum*. (A, From Engelkirk P. G., et al. (1992). *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.)

F. nucleatum and *C. difficile* fluoresce chartreuse (see Fig. 22.13B). *Veillonella* spp. often fluoresce red, but the fluorescence is dependent on the culture medium. It is weaker than the fluorescence produced by pigmented species of *Porphyromonas* and *Prevotella* and fades completely if the colonies are exposed to air for 5 to 10 minutes. Table 22.11 lists the fluorescence characteristics of commonly isolated anaerobic bacteria.

Catalase test

To perform a catalase test, a plastic, disposable inoculating loop or wooden applicator stick is used to place some of the colony onto a small area of a glass microscope slide. A drop of 15% hydrogen peroxide is added; the production of bubbles of oxygen gas is a positive result. Among other uses, the catalase test is valuable in differentiating aerotolerant strains of *Clostridium* (catalase negative) from *Bacillus* (catalase positive). In some anaerobic species, catalase is an inducible enzyme. The bacteria should be exposed to room air for about 20 minutes before testing.

Table 22.11 Fluorescence under long-wave ultraviolet light

Organism	Color of fluorescence
<i>Prevotella</i> (pigmented)	Brick red
<i>P. bivia</i> , <i>P. disiens</i>	Light orange to pink (coral)
<i>Porphyromonas</i>	Brick red (some no fluorescence)
<i>Fusobacterium</i>	Chartreuse (yellow/green)
<i>Veillonella</i>	Red but fades rapidly
<i>Clostridium ramosum</i>	Red
<i>C. innocuum</i> , <i>C. difficile</i>	Chartreuse
<i>Eggerthella lenta</i>	Red or no fluorescence

Spot indole test

The spot indole test uses a small piece of filter paper saturated with *p*-dimethylamino cinnamaldehyde. An inoculating loop or wooden applicator stick is used to transfer some growth from the culture plate onto the saturated filter paper. Rapid development of a blue or green color indicates a positive test result (production of indole from the amino acid tryptophan), whereas a pink or orange color indicates a negative test result. The spot indole test also can be performed directly on a pure culture plate. The spot indole test is useful in identifying *C. acnes* (indole positive) from the similar *Propionibacterium* spp. (indole negative).

Urease test

A rapid urease test can be accomplished by adding a Wee-Tab urease test tablet (Key Scientific Products, Stamford, TX) to 1 mL of distilled water. The isolate is then heavily inoculated into the water and incubated at 37° C. A positive reaction can occur within 15 minutes, but the tube must be held for up to 6 hours before a true negative reaction is determined. Rapid urea broths are also available from various manufacturers. *C. sordellii* is the only *Clostridium* species that is urease positive.

Motility test

Motility may be determined by wet mount using either very young (4–6 hours old) broth cultures or 24- to 48-hour-old colonies on agar. Using a wooden applicator stick, a small portion of a colony should be touched to a drop of saline on a microscope slide. A coverslip is placed over the drop, and the slide is examined with a light microscope. A positive motility test result is indicated when organisms exhibit purposeful movement, which should not be confused with Brownian motion. Motile gram-negative anaerobes include some *Campylobacter* spp. (e.g., *Campylobacter concisus*, *C. curvus*, and *C. rectus*) and *Mobiluncus* spp., among many others.

Special potency antimicrobial disks

Although the Gram stain is helpful in the initial identification of an anaerobic isolate, certain *Clostridium* spp. can stain pink and thus appear to be gram-negative bacilli. To determine the true Gram stain reaction of the isolate, special potency disks can be used. These disks—kanamycin (1000 µg), vancomycin (5 µg), and colistin (10 µg)—are used for identification purposes and are not meant to predict treatment options for the physician (Fig. 22.14).

Fig. 22.14 Disks to add to the pure culture–subculture plate. *Clostridium*-like organisms are large, unbranched, gram-positive rods, with or without spores. Not all clostridia are large, and not all clostridia will stain as gram-positive rods. CL, Colistin (10 µg); K, kanamycin (1000 µg); SPS, sodium polyanethol sulfonate; V, vancomycin (5 µg).

The disks are placed on the heavily inoculated area of the plate, usually the first quadrant of the subculture plate. Disks of the proper potency must be pressed firmly to the surface of the plate to ensure uniform diffusion of the agent into the medium. The disk results for *C. ramosum* are shown in Fig. 22.15. Other disks, as described later, may be used for identification purposes. Disk results are interpreted as shown in Table 22.12.

Sodium polyanethol sulfonate disk

A sodium polyanethol sulfonate (SPS) disk aids in the identification of anaerobic gram-positive cocci. An SPS-sensitive, gram-positive anaerobic coccus can be presumptively identified as *Peptostreptococcus anaerobius*, whereas an SPS-resistant, spot indole-positive, gram-positive anaerobic coccus can be presumptively identified as *Peptoniphilus asaccharolyticus*.

Nitrate disk

The nitrate reduction disk test is a miniaturized version of the conventional nitrate reduction test. This determines an organism's ability to reduce nitrate to nitrite or nitrogen gas.

Bile disk

This disk can be used to determine an organism's ability to grow in the presence of relatively high concentrations (20%) of bile; however, it is not necessary if BBE agar is used as a

Fig. 22.15 Typical special potency antimicrobial disk results for *Clostridium ramosum*, susceptible to vancomycin (left) and kanamycin (right) and resistant to colistin (center). (Courtesy Anaerobe Systems, Morgan Hill, CA.)

primary plating medium. The bile disk may be added to the anaerobic subculture plate whenever the Gram stain reveals the isolate to be a gram-negative bacillus. Good growth on a BBE agar plate or growth in 20% bile indicates bile tolerance. A bile-tolerant, gram-negative anaerobic bacillus indicates that the isolate is likely a member of the *B. fragilis* group.

Table 22.12 Interpretation of special potency antimicrobial disk results

Vancomycin ^a	Kanamycin ^b	Colistin ^c	Interpretation
S	V	R	Probably a pink-staining, gram-positive bacillus such as <i>Clostridium ramosum</i> or <i>C. clostridioforme</i> ; however, if the kanamycin result is resistant, it could be a <i>Porphyromonas</i> sp.
S	R	R	<i>Porphyromonas</i> sp.
R	R	R	Probably a member of the <i>Bacteroides fragilis</i> group, <i>Parabacteroides</i> sp., or <i>Alistipes</i> sp. but could be a <i>Prevotella</i> sp..
R	V	V	<i>Prevotella</i> sp.
R	R	S	Probably a <i>Prevotella</i> sp.
R	S	S	<i>Bilophila wadsworthia</i> , <i>Fusobacterium</i> sp., <i>Sutterella</i> sp., or <i>Tannerella</i> sp.

^aVancomycin, 5μg.^bKanamycin, 1000μg.^cColistin, 10μg.

R, Resistant; S, susceptible (a zone of inhibition ≥10 mm is considered susceptible); V, variable.

Fig. 22.16 Positive lecithinase reaction on egg yolk agar. The reaction occurs within the agar. *Clostridium perfringens* is shown here. (Courtesy Anaerobe Systems, Morgan Hill, CA.)

Lecithinase, lipase, and proteolytic reactions

An EYA plate can be used to determine the activities of lecithinase, lipase, and proteolytic enzymes. These reactions are of value in identifying many species of clostridia. Lecithinase cleaves lecithin found in egg yolk, releasing insoluble fat (diglyceride) that produces an opaque zone around the colony. This opacity is actually in the medium and is not a surface phenomenon (Fig. 22.16). Lipases hydrolyze triglycerides and diglycerides to fatty acids and glycerol. Lipase-positive organisms produce a colony covered with an iridescent, multicolored sheen, sometimes described as resembling the appearance of gasoline on water or mother of pearl. This multicolored sheen also can appear on the surface of the agar in a narrow zone around the colony. In contrast with the lecithinase reaction, the lipase reaction is essentially a surface phenomenon (Fig. 22.17).

Organisms that produce proteolytic enzymes (proteases) have a completely clear zone, often quite narrow, around their colonies. Proteolysis is best observed by holding the plate up to a strong light source. It is reminiscent of the complete clearing seen with β -hemolytic organisms on SBA plates.

Fig. 22.17 Positive lipase reaction on egg yolk agar. The reaction occurs on the surface of colonies and surrounding medium. A positive reaction by *Fusobacterium necrophorum* is shown here. (Courtesy Anaerobe Systems, Morgan Hill, CA.)

Presumptive identification of gram-positive anaerobes

Some gram-positive anaerobes can also be presumptively identified with simple procedures (Table 22.13). None of these organisms will grow on BBE agar or LKVB agar medium, so identification is based on the colony appearance on nonselective anaerobic blood agar and EYA.

- Large, irregular-shaped colonies on SBA demonstrating a double zone of β -hemolysis can be identified as *C. perfringens* (Fig. 22.18). These organisms will stain as large, boxcar-shaped bacilli.
- Large, flat colonies that produce a so-called *barnyard* or *horse stable* odor and fluoresce chartreuse (brilliant yellow-green) under long-wave UV light can be identified as *C. difficile*.

Table 22.13 Presumptive identification of gram-positive anaerobes*

Identification	Colony morphology on blood agar	Cellular morphology	Spot indole
<i>Clostridioides difficile</i>	Large, flat colonies; barnyard odor, characteristic fluorescence	Thin rods, rare spores	Negative
<i>Clostridium perfringens</i>	Large, irregular-shaped, double zone of β -hemolysis	Boxcar, large, square rods	Not done
<i>C. septicum</i>	Smoothly swarming	Thin rods, subterminal spores	Negative
<i>C. sordellii</i>	Very large, lobate, irregular, flat	Thin rods, subterminal spores	Positive
<i>C. tetani</i>	Smoothly swarming but slow growing	Swollen terminal spores	Positive
<i>Cutibacterium acnes</i>	Small, opaque, enamel white, circular (catalase-positive)	Coryneform rods	Positive
AGPC	Small, peaked, circular	Cocci, pairs and chains	Varies depending on species

*Additional information about presumptive identification of aerobes and facultative anaerobes can be found in Clinical and Laboratory Standards Institute. (2008). *Abbreviated identification of bacteria and yeast: approved guidelines (2nd ed.)*. CLSI document M35-A2. Wayne, PA: Clinical and Laboratory Standards Institute. AGPC, Anaerobic gram-positive cocci.

Fig. 22.18 Double zone of hemolysis produced by *Clostridium perfringens*—inner zone of complete β -hemolysis and outer zone of partial β -hemolysis. (Courtesy Anaerobe Systems, Morgan Hill, CA.)

- A rapidly growing colony exhibiting smooth swarming (as opposed to the waves observed with *Proteus*) and staining as thin rods with subterminal spores is likely to be *C. septicum*. Colonies often show β -hemolysis at 48 hours.
- Small, peaked, circular colonies appearing after 24 hours that stain as gram-positive cocci can be considered *Peptostreptococcus* spp. The CLSI M35-A2 document suggests continued use of the terms *Peptostreptococcus* spp. or *anaerobic gram-positive cocci* as a presumptive identification rather than identifying these organisms with the newer nomenclature.
- *Peptococcus niger* produces colonies that are initially black to olive green and become light gray when exposed to air, but it is only rarely isolated from clinical specimens.
- Small, opaque colonies that are catalase and indole positive and stain as coryneform rods can be identified as *C. acnes*.

Case check 22.3

In the Case in Point, a Gram-stained smear of the patient's leg wound revealed boxcar-shaped, gram-positive rods suggestive of clostridia. The presence of large gram-positive bacilli with colonies exhibiting a double zone of β -hemolysis in the absence of organisms recovered on aerobic cultures of the specimen is sufficient to report a presumptive identification of *C. perfringens*.

Presumptive identification of gram-negative anaerobes

Using Gram stain results, growth characteristics on primary plating media (e.g., nonselective anaerobic blood agar, BBE agar, KVLB agar), and a few rapid tests, many gram-negative anaerobes can be presumptively identified, often within 24 hours of inoculation (Table 22.14).

- Growth of large (>1 mm) gray-black colonies on BBE agar with growth on KVLB agar after an overnight incubation is sufficient to identify an isolate as a member of the *B. fragilis* group (Fig. 22.19).
- Translucent pitting colonies observed on the anaerobic blood agar plate, with no growth observed on BBE or KVLB agar, are characteristic of *Campylobacter (Bacteroides) ureolyticus*.
- Translucent colonies with a black fish-eye center observed on BBE agar (usually at 48 to 72 hours) can be used to presumptively identify *Bilophila wadsworthia* (Fig. 22.20).
- Ground-glass or breadcrumb-like colonies of long, slender, gram-negative rods with pointed ends are usually *Fusobacterium nucleatum* (Fig. 22.21).
- Organisms that grow on anaerobic blood agar and KVLB agar but not BBE agar and fluoresce brick red can be identified as *Prevotella*.
- Small, translucent or opaque colonies of tiny gram-negative cocci or diplococci can be identified as *Veillonella*.

Definitive identification of anaerobic isolates

For sterile site and some surgical isolates, it is important for the laboratory to provide full identification. A variety of

Table 22.14 Presumptive identification of gram-negative anaerobes^a

Identification	Colony morphology on blood agar or KVLB agar	Colony morphology on BBE agar	Cellular morphology	Spot indole
<i>Bacteroides fragilis</i> group	Large (>1 mm)	Large, convex, black gray	Regular	Not done
<i>Campylobacter ureolyticus</i>	Translucent, pitting (some)	No growth	Tiny rods or coccobacilli	Negative
<i>Bilophila wadsworthia</i>	Tiny, translucent	Translucent, with black center at 72 hours	Regular to filamentous	Negative
<i>Fusobacterium nucleatum</i>	Ground glass or breadcrumb	No growth	Fusiform, thin with pointed ends	Positive
<i>Porphyromonas</i>	Small, translucent or opaque, brick red fluorescence on blood agar, no growth on KVLB agar	No growth	Tiny coccobacilli	Positive
<i>Prevotella intermedia</i>	Small, translucent or opaque, brick red fluorescence on blood agar and KVLB agar	No growth	Tiny coccobacilli	Positive
<i>Veillonella</i>	Small, translucent or opaque, brick red fluorescence on blood agar, no growth on KVLB agar	No growth	Tiny diplococci	Negative

^aAdditional information about presumptive identification of aerobes and facultative anaerobes can be found in Clinical and Laboratory Standards Institute. techniques can be used to make a definitive identification (see Table 22.9). Many clinical microbiology laboratories use one of the commercially available biochemical-based or preexisting enzyme-based minisystems for making definitive identifications, but it is important to remember that none of these will identify all anaerobes that could potentially be isolated from clinical specimens. Most are designed to identify anaerobes that are most frequently encountered in clinical specimens. It is far more important for a system to identify these organisms than to identify obscure anaerobes that are only rarely isolated from clinical specimens or involved in infectious processes.

Fig. 22.20 Appearance of *Bilophila wadsworthia* on *Bacteroides bile esculin* agar. Note the fish-eye appearance of the colonies.

Biochemical-based multitest systems

A commercially available alternative to conventional tubed media is the biochemical-based identification system Analytical Profile Index (API; bioMérieux, Durham, NC). The API 20A system provides many of the same tests as conventional anaerobic systems but in the form of a plastic strip. Other systems are commercially available. The biochemical-based multitest systems are easier and faster to inoculate than a conventional system of plates and tubes. They require anaerobic incubation and larger model anaerobic jars. Some of the commercially available bags and pouches can be used to incubate biochemical-based trays and strips if an anaerobic chamber is not available. After 24 to 48 hours of incubation, test results are read, a code number is generated for each isolate, and identification is determined from an electronic database. It should be noted that the databases might not contain all the anaerobes that could be isolated from clinical specimens.

Fig. 22.21 Gram-stained appearance of *Fusobacterium nucleatum* subsp. *nucleatum* illustrating the fusiform morphology of this organism ($\times 1000$). (Courtesy S. L. Bartley, J. D. Howard, and R. Simon, Centers for Disease Control and Prevention, Atlanta, GA.)

Preformed enzyme-based systems

Many commercial identification systems are based on the presence of preformed (preexisting) bacterial enzymes. Because these systems do not depend on enzyme induction or bacterial growth, the results are available in about 4 hours. The small plastic panels or cards are easy to inoculate at the bench and do not require anaerobic incubation. Most of the systems generate code numbers, which are referenced in a manufacturer-supplied database. Like the biochemical-based multitest systems, these systems are primarily of value for identifying only the most commonly isolated anaerobes. One potential pitfall with these systems is that the database is sometimes divided by Gram-staining characteristics of the organism. Hence, it is vital to have an accurate Gram stain interpretation to arrive at an accurate identification. Special potency disks to determine the true Gram stain reaction and morphology of an organism can play a major role in the use of the preformed enzyme-based identification systems.

Preexisting enzyme-based systems include the VITEK ANI card (bioMérieux), AN-IDENT (bioMérieux), MicroScan rapid anaerobe identification panel (Beckman Coulter, Brea, CA), BBL Crystal anaerobe identification system (BD Diagnostic Systems), and the RapID-ANA II system (Thermo Fisher Scientific, Waltham, MA) shown in Fig. 22.22. In general, these systems use the same or similar substrates. They contain a number of nitrophenyl and naphthylamide compounds, colorless substances that produce yellow or red products, respectively, in the presence of appropriate enzymes. The results of some of these systems can be read via instrumentation. In performance evaluation studies, preformed enzyme-based and biochemical-based multitest systems were reported to have difficulty identifying gram-positive non-spore-forming bacilli, gram-positive anaerobic cocci, and some clostridia. For this reason, these methods are being replaced by MALDI-TOF mass spectrometry.

Cellular fatty acid analysis by high-resolution gas-liquid chromatography

Cellular fatty acid analysis is another method of identifying anaerobes. The term *cellular fatty acid* refers to fatty acids and

Fig. 22.22 RapID ANA-II preformed enzyme system (Thermo Fisher Scientific, Waltham, MA). This is one of many systems available for rapid definitive identification of commonly isolated anaerobes.

related compounds (e.g., aldehydes, hydrocarbons, dimethylacetals) present within organisms as cellular components. Cellular fatty acids are coded for on bacterial chromosomes, as opposed to plasmids, and are not affected by simple mutations or plasmid loss. Thus the fatty acid composition of a particular organism is relatively stable when the organism is grown under specific growth conditions—medium, incubation temperature, and time. Although fatty acid profiles can be identified manually, computerized, high-resolution gas-liquid chromatography (GLC) and specialized software programs are available to analyze cellular fatty acids of unknown bacteria and compare the results with patterns of known species.

The Sherlock microbial identification system (MIDI, Newark, DE) is a fully automated gas chromatography system that can be used to identify bacteria (including anaerobes) and yeasts (see Chapter 11). The organism is grown in pure culture on standardized medium. The bacterial cells are saponified to release the fatty acids from the bacterial lipids. After extraction, the methyl esters are analyzed by GLC. A chromatogram depicting the unknown organism's fatty acid composition is compared with a computer database of fatty acids of known anaerobes. Because no subjective interpretations are involved, the identifications are objective and highly reproducible.

Matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry

Most recently, bacterial identification has been revolutionized by the use of mass spectrometry. Specifically, a technique called *matrix-assisted laser desorption/ionization–time-of-flight* (MALDI-TOF) mass spectrometry measures the mass-to-charge ratio of ionized particles such as proteins from an organism (see Chapter 11). The technique produces a proteomic fingerprint that can be compared with reference strains. Results can be obtained in minutes, and this process has the potential of rapid identification of anaerobes without the need for an

aerotolerance test to be performed. However, the database for anaerobes is still somewhat limited, with only the most commonly encountered anaerobes identified.

16S Ribosomal RNA gene sequencing

Anaerobes that are difficult to identify often can be definitively identified using 16S rRNA gene sequencing. The 16S rRNA gene, ribosomal deoxyribonucleic acid (rDNA), has highly conserved and highly variable regions that can be used for microbial identification. The DNA is first extracted from the organism; the target segment of about 500 base pairs is amplified through polymerase chain reaction technology and then sequenced on an automated sequencer. The resulting nucleotide sequence is compared with known sequences in public databases such as GenBank, a repository of sequences maintained by the National Institutes of Health. The MicroSeq microbial identification system (Applied Biosystems, Foster City, CA) has kits and an electronic database that can be used for bacterial or fungal identification. The results can be obtained in approximately 5 hours.

Identification of *Clostridium* and *Clostridioides* species

An identification algorithm for some *Clostridium* spp. is shown in Fig. 22.23. Identification of clinically encountered clostridia using cultural and biochemical characteristics is summarized in Table 22.15. The clostridial cell wall structure is similar to that of other gram-positive bacteria. However, some species appear gram variable, and some (e.g., *C. ramosum* and *C. clostridioforme*) routinely stain gram negative. The vancomycin special potency antimicrobial disk set up at the same time as the aerotolerance test is used to determine the true Gram stain reaction of a pink-staining anaerobic bacillus. Gram-positive clostridia are always susceptible to vancomycin.

Certain cultural characteristics can be used initially to identify clostridial isolates. As noted, a boxcar-shaped, gram-positive anaerobic bacillus that produces a characteristic double zone of hemolysis on SBA can be presumptively identified as *C. perfringens*. A double zone of hemolysis appears as an inner zone of complete β -hemolysis and an outer zone of

*Boxcar-shaped bacilli; lecithinase positive; reverse Christie, Atkins, Munch-Petersen (CAMP) test positive; subterminal spores, but spores rarely observed.

†Produces chalk-white colonies on egg yolk agar.

Fig. 22.23 Identification of *Clostridium* spp. Use this chart for organisms fulfilling the following three criteria: (1) anaerobic, (2) gram positive, and (3) spore former. (From Mangels, J. I. [1998]. *Anaerobic bacteriology*. In H. D. Isenberg [Ed.], *Essential procedures for clinical microbiology*. Washington, DC: American Society for Microbiology.)

<i>C. tetani</i>	–	+	–	–	+	T	+	– ⁺	–	–	–	+	–	–

^aCurrently named *Clostridioides difficile*.ST, Subterminal; T, terminal; (T), variable but usually terminal; –ST, usually not observed but subterminal when seen; +[–], most strains positive; –⁺, most strains negative.Modified from Engelkirk, P. G., et al. (1992). *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.

partial β -hemolysis because of two different hemolysins (see Fig. 22.18). A swarming, gram-positive, anaerobic bacillus with terminal spores is probably *C. tetani*, whereas one with subterminal spores is most likely *C. septicum*. EYA is useful for detecting lecithinase, lipase, and proteolytic enzymes produced by some clostridia. Lecithinase-positive clostridia include *C. bifermentans*, *C. sordellii*, *C. perfringens*, and *C. novyi* type A. Some lipase-positive clostridia are *C. botulinum*, *C. novyi* type A, and *C. sporogenes*.

C. sordellii is the only member of the clostridia to exhibit urease activity. *C. bifermentans* and *C. sordellii* are spot indole positive. Finally, it is important to remember that *C. tertium* will grow minimally on the aerotolerance plate and can be mistaken for a facultative anaerobe. However, growth on the anaerobic subculture plate will exhibit much heavier growth than on the aerotolerance test plate.

Clostridioides difficile can be recovered from feces by inoculating a cycloserine–cefotaxime–fructose agar (CCFA) plate. CCFA is a selective and differential medium for the recovery and presumptive identification of *C. difficile*. On CCFA, *C. difficile* produces yellow ground-glass colonies; the originally pink agar turns yellow in the vicinity of the colonies because of the fermentation of fructose. In reduced conditions, the indicator, neutral red, turns yellow in the presence of an acid pH. Although other organisms may grow on CCFA, their colonies are smaller and do not resemble the characteristic colonies of *C. difficile*. In addition, *C. difficile* has a characteristic odor, resembling a horse stable, and colonies on blood agar fluoresce chartreuse under UV light.

Organisms that are isolated must be tested for toxin production because a small percentage of the human population can carry *C. difficile* as normal biota, and some isolates may not be toxin producers. Culture for *C. difficile* has largely been replaced by assays designed to detect the toxins produced by the organism in feces or nucleic acid amplification tests (NAATs). The cell culture cytotoxicity assay detects toxin B in fecal samples by tissue culture; however, this assay is technically demanding and can take 2 to 3 days for results to be obtained. A number of rapid detection tests are available that can detect toxin A, toxin B, the enzyme glutamate dehydrogenase (GDH), or a combination of *C. difficile* toxins and GDH. Many of the kits use enzyme immunoassay (EIA) methods. Glutamate dehydrogenase is not a virulence factor, but it is an enzyme frequently associated with *C. difficile*. A negative glutamate dehydrogenase assay can be used as rapid screening to rule out CDAD; however, a positive glutamate dehydrogenase assay should be confirmed as positive for *C. difficile* toxins by more specific assays. NAATs, either as a stand-alone test or as part of a multiplex diarrheal pathogen panel, can rapidly determine the presence of toxin A and toxin B genes in feces and are rapidly becoming the new gold standard for the detection of toxin-producing *C. difficile*.

A study of 81 patients with symptoms suggestive of CDAD compared three NAATs and two non-NAATs for the detection of CDAD. The authors reported sensitivities of 88.5% to 96.2% for the NAATs and 42.3% and 61.5% for the non-NAATs. The NAATs detected 34.7% more cases

Table 22.16 Characteristics of some clinically encountered gram-positive non-spore-forming anaerobic bacilli

of CDAD than the non-NAAT methods. The specificity for all five assays ranged from 96.4% to 100%. Because patients with formed stools are rarely positive for CDAD, EIA and NAATs should not be performed on these types of specimens.

Identification of anaerobic non-spore-forming, gram-positive bacilli

Identifying characteristics of clinically encountered non-spore-forming, gram-positive bacilli are listed in Table 22.16. In general, non-spore-forming, gram-positive bacilli are difficult to identify because the preformed enzyme system databases often do not contain many of the less commonly isolated species. Sequencing of the 16S rDNA gene has been used recently to reclassify many of these organisms into new genera. MALDI-TOF mass spectrometry databases are being continually improved to identify these organisms.

Actinomyces spp.

Actinomyces spp. are straight to slightly curved bacilli of differing lengths, from short rods to long filaments. Short rods may have clubbed ends and may be seen in diphtheroid arrangements, short chains, or small clusters. Longer rods and filaments may be straight or wavy and branched. Although the *Actinomyces* are gram positive, irregular staining can produce a beaded or banded appearance, much like that seen with *Nocardia* spp. The typical branching, filamentous, Gram-stained appearance of an *Actinomyces* sp., depicted in Fig. 22.2, is referred to as *Actinomyces*-like.

Members of the genus *Actinomyces* are seldom obligate anaerobes. However, some are fastidious, requiring special vitamins, amino acids, and hemin for adequate growth.

Fig. 22.24 Appearance of *Actinomyces israelii* showing the molar tooth colonies typical for this anaerobe.

Young *Actinomyces* colonies are frequently spiderlike or wooly, whereas older colonies of *A. israelii* usually have a molar tooth appearance (Fig. 22.24). Depending on the species, colonies may be red, pink, tan, yellow, white, or grayish. Approximately 25 species have been isolated from human specimens.

Bifidobacterium spp.

Bifidobacterium spp. are variable in shape, ranging from coccobacilli to long branching rods. The ends of the cells may be pointed, bent, club-shaped, spatulated, or bifurcated (forked). Cells may appear singly or in chains and as starlike aggregates, V arrangements, or palisade clusters. Colonies of *Bifidobacterium* spp. are convex, entire, and cream to white, smooth, glistening, and soft.

Fig. 22.25 Gram-stained appearance of *Cutibacterium acnes*, illustrating the term diphtheroid ($\times 1000$). (Courtesy S. L. Bartley, J. D. Howard, and R. Simon, Centers for Disease Control and Prevention, Atlanta, GA.)

Lactobacillus spp.

Colony morphology of the lactobacilli is greatly varied, with some species appearing as pinpoint α -hemolytic colonies on SBA. Others have been described as medium in size, with a rough appearance and gray color. Lactobacilli are catalase negative and, unless a Gram stain is performed, differentiation from *Streptococcus* sp. viridans group is difficult.

Propionibacterium and Cutibacterium spp.

Propionibacterium and *Cutibacterium* spp. are pleomorphic rods with a diphtheroid appearance. The Gram-stained appearance of *C. acnes* is shown in Fig. 22.25. Because *C. acnes* is a common member of the skin microbiota, it is frequently isolated from blood culture bottles as a contaminant. However, *C. acnes*, like coagulase-negative staphylococci, can cause subacute bacterial endocarditis, prosthetic joint infection, and bacteremia and thus is not always a contaminant. A gram-positive anaerobic diphtheroid that is both catalase and spot indole positive can be presumptively identified as *C. acnes*.

Pseudopropionibacterium propionicum can cause actinomycosis. This organism ranges considerably in size and shape, ranging from coccoid and short diphtheroidal rods to long, branched filaments. Individual cells may be of uneven diameter and have distended or clubbed ends. As the genus name implies, propionic acid is a major metabolic end product of *Pseudopropionibacterium* and *Propionibacterium* spp.

Identification of anaerobic gram-negative bacilli

Key tests for the identification of gram-negative anaerobic bacilli are listed in Table 22.17. Definitive identification of many of the commonly occurring gram-negative anaerobes can be accomplished by the preformed enzyme systems or MALDI-TOF mass spectrometry, so reliance on more extensive methods is usually not necessary.

Bacteroides spp.

The genus *Bacteroides* was divided previously into bile-tolerant and bile-sensitive species. However, most of the

bile-sensitive species were transferred to the genera *Prevotella* and *Porphyromonas*. Bile-tolerant species grow in the presence of 20% bile, so colonies will be present on BBE agar. They will exhibit robust growth on KVLB agar.

Bacteroides fragilis group and other bile-resistant Bacteroides

Bile-tolerant *Bacteroides* spp. include members of the *B. fragilis* group and *Parabacteroides* spp. Members of the *B. fragilis* group, which contains more than 50 species, are especially pathogenic. The most clinically relevant are *B. fragilis*, *B. thetaiotaomicron*, and *B. ovatus*. *B. fragilis* is the most common species of anaerobic bacteria isolated from infectious processes of soft tissue and anaerobic bacteremia and is responsible for more than 60% of infections caused by the *B. fragilis* group. *B. thetaiotaomicron* is the next most frequently encountered member of the *B. fragilis* group and often exhibits the highest degree of antimicrobial resistance. Gram-stained smears of *Bacteroides* spp. colonies reveal gram-negative coccobacilli or bacilli, but cells in broth cultures are frequently pleomorphic. The Gram-stained appearance of a typical *Bacteroides* species is shown in Fig. 22.26.

Colonies of the *B. fragilis* group on a BBE agar plate are usually brown to black, on the originally pale yellow medium, and a minimum of 1 mm in diameter at 24 hours. Good growth is the result of bile tolerance, and darkening of the medium is caused by esculin hydrolysis. A dark precipitate (stippling) in the medium around the areas of heavy growth is suggestive of the species *B. fragilis*, although some strains of *Bacteroides ovatus* also cause stippling. The appearance of *B. fragilis* group organisms on a biplate of BBE agar and KVLB agar is shown in Fig. 22.19. Caution must be taken, however, when interpreting results obtained on BBE agar. *B. vulgatus*, a member of the *B. fragilis* group, often does not hydrolyze esculin and therefore may not produce a brown to black discoloration of the medium. Depending on the commercial source, age, and storage conditions of the medium, other organisms, such as *F. mortiferum*, *Klebsiella pneumoniae*, *Enterococcus* spp., and some yeasts, may also grow on BBE agar. Their colony size (tends to be smaller), Gram stain morphology, and aerotolerance will aid in the recognition of these other organisms.

Characteristics of the most commonly isolated members of the *B. fragilis* group can be found in Table 22.17. All members will be resistant to colistin, kanamycin, and vancomycin special potency disks. The members of the *B. fragilis* group can be divided into those that produce indole (e.g., *B. thetaiotaomicron*, *B. uniformis*, and *B. ovatus*) and those that do not (e.g., *B. fragilis*, *B. vulgatus*, and *B. caccae*). Catalase activity can be found in *B. fragilis*, *B. ovatus*, *B. thetaiotaomicron*, and *P. distasonis*.

Bilophila sp.

Bilophila wadsworthia is a bile-resistant anaerobe that will grow on BBE agar with a characteristic fish-eye appearance (see Fig. 22.20), and it also will grow on KVLB agar. The organism is strongly catalase positive and nitrate positive.

Prevotella spp.

Prevotella spp. will grow on KVLB agar but not on BBE agar. They are resistant to vancomycin and kanamycin but are variable in their susceptibility to the colistin special potency disk. Some species of *Prevotella* produce protoporphyrin, a dark pigment that causes their colonies to become brown to black with

age. Colony pigmentation may take 2 to 3 weeks of incubation before it becomes evident on routine Brucella blood agar plates, but it appears sooner on KVLB agar. Therefore nonpigmented colonies on KVLB agar or Brucella blood agar should be subjected to long-wave UV light, such as with a Wood lamp, to detect the typical brick red fluorescence of pigment-producing *Prevotella* spp. that appears before the brown pigment. The brick red fluorescence under UV light is similar to that shown in Fig. 22.13A. Some species of pigmented *Prevotella* fluoresce colors other than brick red (e.g., brilliant red, yellow, orange, pink orange), and some do not fluoresce at all. Only brick red fluorescence allows presumptive identification of the pigmented *Prevotella* group. *P. intermedia* and *P. loescheii* produce lipase, and *P. intermedia* is spot indole positive. In a Gram-stained smear, *Prevotella* spp. appear as gram-negative coccobacilli or bacilli, very similar to *Bacteroides* spp.

Porphyromonas spp.

Porphyromonas spp. will produce brick red fluorescence under UV light, similarly to *Prevotella*, but some species do not fluoresce. Because most *Porphyromonas* strains are susceptible to vancomycin, they will not grow on KVLB agar; however, in contrast with *Prevotella*, they are resistant to colistin with the special potency disks. Most *Porphyromonas* spp. are spot indole positive.

Campylobacter ureolyticus group

The *Campylobacter ureolyticus* group consists of bile-sensitive and bile-tolerant nonpigmented organisms (see Table 22.17). Reports have shown that the so-called *pitting anaerobes* of the *C. ureolyticus* group, which includes *C. ureolyticus*, *C. gracilis*, *C. curvus*, *C. rectus*, and *Sutterella wadsworthensis*, are actually microaerophiles rather than obligate anaerobes. One useful identifying characteristic of this group is the colony appearance. Many of the organisms have colonies that appear to pit the agar. However, not all strains pit agar, and among those strains that do, not all colonies will appear to be pitting, so they may resemble a mixed culture. Growth in broth is enhanced by the addition of formate or fumarate, a characteristic unique to this group. The members of this group are positive in the nitrate test, whereas *C. ureolyticus* is able to hydrolyze urea and is spot oxidase positive. *C. ureolyticus*

is bile sensitive, *Sutterella* spp. are bile tolerant, and the other campylobacters are variable in bile sensitivity.

Fusobacterium

Fusobacterium spp. are often described microscopically as long, thin, tapered rods, a morphology characteristically referred to as *fusiform*. It is important to note, however, that only *F. nucleatum* has cells that are consistently fusiform in shape, and clinically encountered bacteria that are fusiform in shape are not necessarily *Fusobacterium*. The Gram-stained appearance of *F. nucleatum* is shown in Fig. 22.21. Other fusobacteria, such as *F. mortiferum*, appear pleomorphic and exhibit globular forms, swellings, and other bizarre shapes. The pleomorphism of *F. mortiferum* is depicted in Fig. 22.27. Organisms other than fusobacteria can also have fusiform-shaped cells, such as *C. gracilis*, *Bacteroides forsythus*, and microaerophilic *Capnocytophaga*.

Fusobacteria are resistant to vancomycin but susceptible to colistin and kanamycin with the special potency disks. However, all except *F. nucleatum* will grow on KVLB agar because the level of kanamycin is reduced from that of the special potency disk. With the exception of *F. mortiferum*, the fusobacteria are indole positive, and all will fluoresce chartreuse under long-wave UV light. In addition, *F. necrophorum* is positive for lipase when grown on EYA.

Identification of anaerobic cocci

An algorithm depicting the presumptive identification of the anaerobic gram-positive cocci is shown in Fig. 22.28; the Gram stain appearance of a typical anaerobic coccus is seen in Fig. 22.29. Phenotypic characteristics used to identify anaerobic cocci are listed in Table 22.18. As noted, presumptive identification of gram-positive anaerobic cocci can be reported as *Peptostreptococcus* spp. or as anaerobic gram-positive cocci. Full identification can be accomplished by preformed enzyme systems; 16S rRNA sequencing and MALDI-TOF mass spectrometry have been shown to identify accurately many of the more commonly isolated anaerobic gram-positive cocci.

A black-pigmented, anaerobic, gram-positive coccus can be identified as *Peptococcus niger*. *Peptostreptococcus anaerobius* can be identified by a zone of inhibition around an SPS disk.

*Some strains of *Peptostreptococcus micros* are susceptible to SPS, but they generally produce smaller zones of inhibition.

†*Anaerococcus* (*Peptostreptococcus*) *hydrogenalis* is also indole-positive but unlike *P. asaccharolyticus* is alkaline phosphatase positive.

Fig. 22.28 Identification of anaerobic gram-positive cocci. Anaerobic gram-positive cocci (AGPC) are susceptible to metronidazole, whereas microaerophilic gram-positive cocci are not. An 80- μ g metronidazole elution disk (BD Diagnostic Systems, Sparks, MD) can be used to determine metronidazole susceptibility. Although metronidazole-resistant strains of AGPC have been reported, they appear to be rare. SPS, Sodium polyanethol sulfonate.

Fig. 22.29 Gram-stained appearance of a *Peptostreptococcus* sp. illustrating the chain formation that occurs with some species of anaerobic gram-positive cocci ($\times 1000$). (Courtesy S. L. Bartley, J. D. Howard, and R. Simon, Centers for Disease Control and Prevention, Atlanta, GA.)

Spot indole-positive isolates are often members of the genus *Peptoniphilus*, with *P. indolicus* identified by a positive nitrate test result. The only urease-positive anaerobic coccus is *Anaerococcus tetradius*. *Finegoldia magna* and *Parvoimonas micra* are similar in biochemical reactions but can be differentiated on the basis of

size; *F. magna* has cocci larger than $0.6\mu\text{m}$, whereas *P. micra* cocci are smaller. *Veillonella parvula* is the only commonly encountered gram-negative coccus, and it can be identified with Gram stain, a positive catalase reaction, and red fluorescence under long-wave UV light. It is also positive for nitrate reduction and is resistant to the vancomycin special potency disk.

Antimicrobial susceptibility testing

Traditionally, the isolation, identification, and susceptibility testing of anaerobes have been slow compared with those of aerobic bacteria isolated from the same specimen. As a result, when health care providers suspect an anaerobic infection, they routinely select a broad-spectrum agent for empiric therapy that will cover most anaerobes, pending outcome of the culture. This practice was based on the fact that many antimicrobial agents could be relied on to have good activity against the most commonly isolated anaerobes. However, resistance to antimicrobial agents has increased in recent years, and the susceptibility patterns of many anaerobes to certain antimicrobial agents can no longer be guaranteed. Antimicrobial resistance has mainly been observed in the *B. fragilis* group but has also been noted to a lesser extent in most of the clinically significant anaerobes.

Table 22.18 Characteristics of some clinically encountered anaerobic cocci

	Gram-stain reaction	Catalase	Indole	Urease	Nitrate reduction	Red fluorescence	Comments
<i>Peptostreptococcus anaerobius</i>	+	—	—	—	— ⁺	—	Inhibited by SPS disk
<i>Parvimonas micra</i>	+	—	—	—	—	—

 Modified from Engelkirk, P. G., et al. (1992). *Principles and practice of clinical anaerobic bacteriology*. Belmont, CA: Star Publishing.

CLSI document M11-A8, *Methods for Antimicrobial Susceptibility Testing of Anaerobic Bacteria* (approved standard), provides guidelines for susceptibility testing of anaerobes. The document suggests that susceptibility testing should be performed when anaerobes are recovered from the following infections:

- Brain abscess
- Endocarditis
- Infection of a prosthetic device or vascular graft
- Joint infection
- Osteomyelitis
- Bacteremia

Because many anaerobe-associated infectious processes are polymicrobial, deciding which anaerobic isolates warrant susceptibility testing is frequently difficult. The CLSI suggests that the following anaerobes, recognized as highly virulent and/or commonly resistant to antimicrobial agents, should be considered for testing:

- *Bacteroides fragilis* group
- *Prevotella*
- *Clostridium*
- *Fusobacterium*
- *Bilophila wadsworthia*
- *Sutterella wadsworthensis*

The CLSI working group suggests that larger laboratories periodically test several of the anaerobes listed here to determine whether the emergence of resistance to certain antimicrobial agents has occurred at their institution. Similarly, if a new antimicrobial agent has been added to the hospital formulary, testing should be performed to determine the agent's range of activity. The microbiology laboratory's decision as to which antimicrobial agents to test should be made after consultation with the hospital's infectious disease practitioners, pharmacists, and antimicrobial stewardship committee. [Table 22.19](#) lists the CLSI recommendations for the antimicrobial agents that should be considered for testing.

Problems in susceptibility testing of anaerobic isolates

Several problems have limited the routine susceptibility testing of anaerobes, including a lack of reproducibility, failure of some anaerobes to grow on or in particular media, difficulty in reading end points with certain methods, and a lack of comparability among methods. Cost and procedure complexity are other factors that inhibit laboratories from performing susceptibility testing of anaerobes.

Susceptibility testing options

CLSI document M11-A8 describes only two methods for susceptibility testing of anaerobes: agar dilution and broth microdilution. Although it is considered the gold standard method, agar dilution is labor-intensive and is not practical for use in smaller clinical laboratories. It is used primarily in reference laboratories and institutions that test large numbers of isolates. Broth microdilution panels are commercially available and can be stored frozen or lyophilized for extended periods. However, the CLSI M11-A8 document suggests that, at present, this method be used for testing members only of the *B. fragilis* group.

The Etest (AB Biodisk, Solna, Sweden) method, described in [Chapter 13](#), is an alternative method for anaerobic susceptibility testing commonly used in clinical microbiology laboratories. Testing can be performed on Mueller-Hinton agar supplemented with 5% sheep red blood cells, and plates can be incubated in anaerobe bags, jars, or chambers. Testing is limited to six antimicrobial agents on one agar plate, which is usually sufficient for most clinical situations. One critical aspect of the Etest procedure is limiting exposure to oxygen during setup and quickly achieving anaerobiasis. This is because the commonly used antimicrobial agent metronidazole is very oxygen sensitive.

Many laboratories amend their anaerobic culture reports with statements suggesting empiric agents that continue to have broad anaerobic activity. These include the carbapenems (e.g., ertapenem, imipenem, meropenem), metronidazole,

Table 22.19 Suggested antimicrobial susceptibility testing for anaerobic bacteria

	Gram-negative anaerobes (including <i>Bacteroides fragilis</i> group)	Gram-positive anaerobes
Primary choices	β -Lactam combination agent (e.g., ampicillin-sulbactam, amoxicillin-clavulanate piperacillin-tazobactam) Clindamycin Carbapenem (e.g., ertapenem, imipenem, meropenem) Metronidazole	Ampicillin or penicillin β -Lactam combination agent (e.g., ampicillin-sulbactam, amoxicillin-clavulanate, piperacillin-tazobactam) Clindamycin Carbapenem (e.g., ertapenem, imipenem, meropenem) Metronidazole
Supplemental choices	Ceftizoxime, ceftriaxone Cefoxitin Moxifloxacin	Cefoxitin, ceftizoxime, ceftriaxone Tetracycline Moxifloxacin

Modified from Clinical and Laboratory Standards Institute. (2012). *Methods for antimicrobial susceptibility testing of anaerobic bacteria: approved standard (8th ed.)*. CLSI document M11-A8. Wayne, PA: Clinical and Laboratory Standards Institute.

and the β -lactam combination antibiotics (ampicillin-sulbactam, amoxicillin-clavulanic acid, piperacillin-tazobactam). This provides health care providers with valuable information about the empiric treatment of anaerobic infections.

Treatment of anaerobe-associated diseases

There are essentially five approaches to the management of anaerobic infections.

Surgical therapy

Because most anaerobic infections are abscesses caused by mixtures of aerobic and anaerobic bacteria, the most important therapy is surgical drainage of the abscess. In less serious infections, this may be the only therapy required. Other surgical procedures include removing dead tissue (debridement), eliminating obstructions, decompressing tissues, releasing trapped gas, improving tissue circulation, and improving tissue oxygenation.

Hyperbaric oxygen

The use of a hyperbaric oxygen chamber to force oxygen into necrotic tissue has been used as adjunct therapy for anaerobic infections for many years and has gained popularity in specialty wound care clinics. Hyperbaric oxygen has also been suggested to be useful therapy for cases of osteomyelitis caused by anaerobes.

Antimicrobial therapy

The primary role of antimicrobial agents is to limit the local and systemic spread of the organisms. Selection of the correct antimicrobial agent depends on a number of factors, including types of organisms involved, known resistance factors, site of the infection, and toxicity of the antimicrobial agent. Although antimicrobial resistance has been observed with almost every agent known to have anaerobic coverage, the

carbapenems, metronidazole, and the β -lactam combination antibiotics continue to have activity against most anaerobes and are used as empiric therapy. Antimicrobial treatment of necrotic abscess is difficult because of poor circulation to the infected site.

Antitoxins

In cases of tetanus and botulism, antitoxins are used to neutralize the effect of neurotoxins produced by *C. tetani* and *C. botulinum*, respectively. Antitoxins are effective against toxin molecules that have not yet bound to host cell receptors.

Fecal microbiota transplant

Recently, refractory CDAD has been treated with replacement of the fecal microbiota. Donor feces can be obtained from a family member or purchased from a fecal transplant bank (OpenBiome, Cambridge, MA) and instilled either through colonoscopy or endoscopy. Although the technique sounds unpleasant, the cure rate of fecal microbiota transplant is over 90% in patients who have undergone numerous treatments with antimicrobials.

Case check 22.4

In the Case in Point, the patient was scheduled for immediate surgical debridement and given broad-spectrum antimicrobial therapy pending culture results. Without proper aggressive therapy, gas gangrene might require amputation. The bacteria can quickly spread, producing a fatal septicemia.

POINTS TO REMEMBER

- Varying amount of oxygen tolerance characterizes microaerophilic and facultative anaerobes and aerotolerant anaerobes, while obligate anaerobes require oxygen-free growth conditions.
- Obligate anaerobes are important in human and veterinary medicine because they can produce serious and often fatal infections and intoxications.

- Aspirates and tissue from sterile sites are more appropriate for anaerobic culture than swabs.
- Anaerobic infections of exogenous origin are usually caused by gram-positive, spore-forming bacilli belonging to the genus *Clostridium*.
- The anaerobes most frequently isolated from infectious processes in humans are those of endogenous origin, such as members of the *B. fragilis* group.
- Factors that commonly predispose the human body to anaerobic infections include trauma of mucous membranes or skin, vascular stasis, tissue necrosis, and decrease in the redox potential of tissue.
- Ports of entry for endogenous anaerobes include mucosal surfaces of oral cavities, GI tract, and GU tract.
- Significant clinical infections caused by anaerobes include mixed microbiota abscesses, tetanus, botulism, myonecrosis, CDAD, and actinomycosis.
- Many types of specimens are unacceptable for anaerobic bacteriology because they are likely to be contaminated with anaerobes of the endogenous microbiota.
- Proper selection, collection, and transport of specimens for anaerobic culture are critical for quality results and maximum recovery of pathogens.
- The anaerobes most commonly associated with infectious processes and those most often isolated from specimens include members of the *B. fragilis* group, certain *Clostridium* spp. (e.g., *C. perfringens*, *C. ramosum*, *C. clostridioforme*, *C. septicum*), *Clostridioides difficile*, *Fusobacterium nucleatum*, *F. necrophorum*, *Cutibacterium acnes*, *Actinomyces israelii*, *Porphyromonas*, *Prevotella*, and the anaerobic gram-positive cocci.
- Presumptive identifications are based on Gram stain reaction and morphology, colony appearance on different media, and results of simple, inexpensive, and rapid test procedures.
- Definitive identifications are commonly made using preformed enzyme-based identification kits, 16S rDNA sequencing, or MALDI-TOF mass spectrometry.
- Susceptibility testing of anaerobes is not recommended for all anaerobic isolates but is warranted for specific types of serious infections and whenever especially virulent or drug-resistant anaerobes have been isolated.
- Recommended methods for anaerobe susceptibility testing include microwell broth dilution panels and the Etest.
- Anaerobe-associated diseases may be treated by surgery, hyperbaric oxygen therapy, antitoxins, and antimicrobial therapy. Refractory CDAD can be treated with fecal microbiota transplant.

LEARNING ASSESSMENT QUESTIONS

1. Match the following infectious diseases with their associated causative organism:
 - _____ Myonecrosis
 - _____ Tetanus
 - _____ Botulism
 - _____ Pseudomembranous colitis
 - _____ Actinomycosis
 - a. *Clostridioides difficile*
 - b. *Clostridium perfringens*
 - c. *Clostridium tetani*
 - d. *Clostridium botulinum*

- e. *Actinomyces* spp.
2. Which organism can live in reduced concentrations of oxygen but prefers an anaerobic environment?
 - a. Capnophile
 - b. Obligate anaerobe
 - c. Facultative anaerobe
 - d. Aerotolerant anaerobe
3. Some anaerobes are particularly susceptible to oxygen because they lack which enzyme?
 - a. Amylase
 - b. β -Lactamase
 - c. Superoxide dismutase
 - d. Glucose-6-phosphate dehydrogenase
4. Which endogenous anaerobes are least likely to be involved in cases of bacteremia?
 - a. *Bacteroides*
 - b. *Clostridium*
 - c. *Eubacterium*
 - d. *Fusobacterium*
5. Which of the following specimens would be unacceptable for anaerobic culture?
 - a. Aspirated pus
 - b. Cerebrospinal fluid
 - c. Tissue from biopsy
 - d. Urethral swab
6. A gram-positive anaerobic bacillus was isolated from a wound specimen and had the following characteristics: double zone of β -hemolysis on sheep blood agar, lecithinase positive, lipase negative, spot indole negative. What is the most likely identification of this organism?
 - a. *Clostridium perfringens*
 - b. *Clostridium ramosum*
 - c. *Clostridium septicum*
 - d. *Clostridium tetani*
7. An anaerobic, pleomorphic, gram-negative bacillus was recovered from a liver abscess. The special potency antimicrobial disks demonstrated that the organism was vancomycin resistant and colistin and kanamycin sensitive. Other results were as follows: chartreuse fluorescence, spot indole positive, and lipase positive. What is the most likely identification of the organism?
 - a. *Fusobacterium mortiferum*
 - b. *Fusobacterium necrophorum*
 - c. *Fusobacterium nucleatum*
 - d. *Fusobacterium varium*

Indicate whether the following statements are true or false:

- _____ 8. Exogenous anaerobes more commonly cause infectious diseases than endogenous anaerobes.
- _____ 9. *Clostridium* spp. are especially easy to identify in Gram-stained smears of clinical specimens because they always appear as gram-positive rods with terminal or subterminal spores.
- _____ 10. Failure to isolate fusiform gram-negative organisms that were observed on a Gram-stained smear of a clinical specimen could indicate that a problem exists with the primary medium used for the isolation of anaerobes or the system being used for anaerobic incubation of primary plates.
- _____ 11. Large, dark colonies (>1 mm) growing on a BBE agar plate at 24 hours can presumptively be called a member of the *Bacteroides fragilis* group.

12. A pleomorphic gram-positive bacillus that is spot indole and catalase positive can be presumptively identified as *Cutibacterium acnes*.
13. Gram-stained smears made from a transtracheal aspirate show gram-positive branching filamentous bacilli. The culture grows colonies on anaerobic Brucella blood agar after 7 days and in thioglycollate broth after 5 days of incubation. Based on these findings, which of the following should be suspected?
- Bacteroides fragilis* group
 - Clostridium*
 - Fusobacterium*
 - Actinomyces* sp.
14. Which of the following organisms is an obligate anaerobic, gram-negative coccus?
- Bacteroides*
 - Veillonella*
 - Peptostreptococcus*
 - Fusobacterium*
15. Which of the following anaerobes is most often associated with antimicrobial resistance?
- B. fragilis* group
 - Clostridium*
 - Bacteroides* sp., not *B. fragilis*
 - Actinomyces* sp.
16. Which of the following is/are indication(s) of the presence of anaerobes?
- A double zone of hemolysis suggestive of *C. perfringens* on sheep blood agar (SBA)
 - A triple zone of hemolysis on SBA incubated anaerobically, suggestive of *C. perfringens*
 - A foul odor on opening the anaerobic jar or bag caused by metabolic end products
 - a and c
17. Anaerobic isolates can be definitively isolated via which method?
- MALDI-TOF mass spectrometry
 - Preformed enzyme-based systems
 - Biochemical-based multitest systems
 - All of the above
18. A 76-year-old male patient in a nursing home is recovering from bacterial pneumonia. The patient has been on an antimicrobial agent regimen for the past 10 days. Subsequently, he exhibits gastrointestinal symptoms consistent with pseudomembranous colitis. Which of the following organisms should be suspected?
- Clostridium perfringens*
 - Clostridioides difficile*
 - Clostridium botulinum*
 - Bifidobacterium* spp.
19. Material from an intestinal abscess produces gray colonies with a brown color in the area around the colonies on a BBE plate incubated anaerobically. There is also a dark precipitate in the medium in the areas of heavy growth. A Gram stain of the colonies reveals gram-negative coccobacilli. What is the presumptive identification of this organism?
- Bacteroides fragilis* group
 - Bacteroides vulgatus*
 - Bacteroides denticola*
 - Peptostreptococcus* sp.
20. An immunosuppressed patient notices sinus tracts that are draining pus. He also notices that there appear to be small, hard "nuggets" in the pus. What disease is he most likely suffering from?
- Gas gangrene
 - Pseudomembranous colitis
 - Actinomycosis
 - Myonecrosis

Bibliography, 542

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics of the genera of spirochetes.
2. Discuss the risk factors associated with relapsing fever infection.
3. Describe the pathogenesis and clinical manifestations of the borrelioses.
4. Compare the causative agents and arthropod vectors of relapsing fever and Lyme borreliosis.
5. Describe the laboratory diagnosis of relapsing fever and how it differs from the diagnosis of other spirochetal diseases in the United States.
6. Justify the use of the two-tiered approach to laboratory diagnosis of Lyme borreliosis.
7. Compare the four human pathogens of the genus *Treponema*.
8. Describe the clinical manifestations of the primary, secondary, and tertiary stages of syphilis.
9. Discuss the epidemiology of leptospirosis in the United States.
10. Evaluate the tests used to diagnose *Treponema pallidum* infections in the clinical laboratory.

KEY TERMS

- | | |
|-----------------------------|--|
| Chancere | Rapid plasma reagin (RPR) test |
| Endemic relapsing fever | Relapsing fever |
| Endemic syphilis | Spirochetes |
| Epidemic relapsing fever | Syphilis |
| Erythema migrans (EM) | Venereal Disease Research Laboratory (VDRL) test |
| Gummas | Weil disease |
| Jarisch-Herxheimer reaction | Yaws |
| Leptospirosis | Zoonoses |
| Lyme borreliosis | |
| Pinta | |

Case in point

A 29-year-old male patient arrived at a local medical clinic in Los Angeles complaining of diarrhea, fever, chills, muscle aches, and headaches. He had returned 2 days earlier after competing in the Eco-Challenge in Malaysian Borneo. During the competition, he completed various events, including mountain biking, caving, climbing, jungle trekking, swimming, and kayaking in freshwater and salt water. He was still recovering from multiple abrasions from the jungle trekking and mountain biking. While kayaking on the Segama River, his kayak capsized, and he inadvertently swallowed several mouthfuls of river water. His two teammates took doxycycline as malaria prophylaxis before and during the race. Neither of them became ill.

Issues to consider

After reading the patient's case history, consider:

- Risk factors for acquiring infectious disease for the patient
- Spirochete agents that cause influenza-like illness and methods to identify or rule out those agents
- Effective prophylaxis, if available, for influenza-like illness caused by spirochetes
- Empiric therapy options

The class Spirochaetia contains four orders: Brachyspirales, Brevinematales, Leptospirales, and Spirochaetales. The order Leptospirales contains the family Leptospiraceae, and the order Spirochaetales contains four families: Borreliaceae, Sphaerochaetaceae, Spirochaetaceae, and Treponemataceae. The family Leptospiraceae contains the genus *Leptospira*, the family Borreliaceae contains the genus *Borrelia*, and the family Treponemataceae contains the genus *Treponema*. These three genera include the causative agents of important human diseases, such as **syphilis** (sexually transmitted); **leptospirosis**, a **zoonoses** (transmitted from animals to humans); and Lyme borreliosis (or Lyme disease) and **relapsing fever**, both of which are vector-borne diseases. There has been a recent resurgence in primary and secondary syphilis as well as the severe disease congenital syphilis in the United States. Leptospirosis is likely a prevalent, underreported disease found worldwide.

Spirochetes are slender, flexuous, helically shaped, unicellular bacteria ranging in size from 0.1 to 0.5 μm wide and from 5 to 20 μm long, with one or more complete turns in the helix. They differ from other bacteria in that they have a flexible cell wall around which several fibrils are wound. These fibrils, termed *periplasmic flagella* (also known as *axial fibrils*, *axial filaments*, *endoflagella*, and *periplasmic fibrils*), are responsible for motility. A multilayered outer sheath resembling the outer membrane of gram-negative bacteria surrounds completely the protoplasmic cylinder (the cytoplasmic and nuclear regions are enclosed by the cytoplasmic membrane-cell wall complex and periplasmic flagella). The spirochetes exhibit various types of motion in liquid media.

Spirochetes are free living or survive in association with animal and human hosts as normal biota or pathogens. In addition, they can use carbohydrates, amino acids, long-chain fatty acids, or long-chain fatty alcohols as carbon and energy sources. Metabolism can be anaerobic, facultatively anaerobic, or aerobic, depending on the species. *Treponema* spp. reproduce via transverse fission, whereas *Leptospira* and *Borrelia* divide by the more common binary fission.

Leptospira

General characteristics

Historically, pathogenic leptospire were identified as *Leptospira interrogans*, and environmental saprophytes were named *Leptospira biflexa*. Currently, the leptospire are divided into serovars (serotypes). More than 200 different serovars of *L. interrogans* sensu lato are recognized. Antigenically related serovars are placed into serogroups, which have no taxonomic standing but are useful for epidemiologic studies. Genetic typing (16S rRNA gene) based on nucleic acid similarities has identified 23 genomospecies that include all of the *Leptospira* serovars. Although genetic typing is taxonomically correct, scientists and health care providers continue to prefer serogroup-based nomenclature. Identification requires determining serovars by serotyping and determining species by nucleic acid sequencing or matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry.

Organisms of the genus *Leptospira* are tightly coiled, thin, flexible spirochetes, 0.1 μm wide and 5 to 15 μm long (Fig. 23.1).

Fig. 23.1 Dark-field image of *Leptospira interrogans* serotype Sejroe Wolffii 3705. The tight coils and bent ends are characteristic of this organism ($\times 1000$). (Courtesy State Laboratories Division, Hawaii Department of Health.)

In contrast with both *Treponema* and *Borrelia* organisms, the spirals are very close together, so the organism may appear to be a chain of cocci. One or both ends of the organism have hooks rather than tapering off. Their motion is rapid translational (back and forth) and rotational.

Electron microscopy reveals a long axial filament covered by a very fine sheath, like treponemes and borreliae. All species have two periplasmic flagella. The organisms cannot be readily stained, but they can be impregnated with silver and visualized. Unstained cells are not visible by bright-field microscopy but are visible by dark-field, phase-contrast, and immunofluorescent microscopy. Leptospire are obligate aerobes.

Virulence factors and pathogenicity

Leptospiral disease in the United States is caused by more than 20 different serovars, the most common of which are Icterohaemorrhagiae, Australis, and Canicola. Some serovars of *L. interrogans* sensu lato and *L. biflexa* sensu lato are pathogenic for a wide range of wild and domestic animals and humans, but the mechanisms of pathogenicity are not well understood. Factors that may play a role in pathogenicity include reduced phagocytosis in the host, a soluble hemolysin produced by some virulent strains, cell-mediated sensitivity to leptospiral antigen by the host, and small amounts of endotoxins produced by some strains. The clinical findings in animals with leptospirosis suggest the presence of endotoxemia.

Infections caused by leptospire

Zoonotic leptospire contaminate water or mud when shed in the urine of infected animals and often enter the human host through small breaks in the skin or intact mucosa. The initial sites of multiplication are unknown. Nonspecific host defenses do not stop multiplication of leptospire, and

leptospiremia occurs during acute illness. Late manifestations of the disease can be caused by the host's immunologic response to the infection.

The incubation period of leptospirosis is usually 10 to 12 days but ranges from 3 to 30 days. Individuals often do not seek treatment because the majority of cases are subclinical or very mild. The clinical presentation is usually abrupt, with nonspecific, influenza-like symptoms, such as fever, chills, headache, severe myalgia, and malaise. The subsequent course is protean, frequently biphasic, and can result in hepatic, renal, and central nervous system (CNS) involvement. The major renal lesion is an interstitial nephritis with associated glomerular swelling and hyperplasia that does not affect the glomeruli. The most characteristic physical finding is conjunctival suffusion, but this is seen in less than 50% of patients. Severe systemic disease (**Weil disease**) occurs in about 5% to 10% of cases and includes renal failure, hepatic failure, and intravascular disease and can result in death. The duration of the illness ranges from less than 1 week to 3 weeks. Late manifestations can be caused by the host's immunologic response to the infection. In patients with a leptospiral bacteremia, immunoglobulin M (IgM) antibodies are detected within 1 week after onset of disease and can persist in high titers for many months. Immunoglobulin G (IgG) antibodies are usually detectable 1 month or more after infection. Convalescent serum contains protective antibodies.

Epidemiology

Leptospira can be free living or associated with colonization of kidneys in animals. The most important hosts are small mammals. Worldwide, leptospirosis is considered the most common zoonosis, causing an estimated over 1 million cases annually. In 2013, leptospirosis was reinstated as a notifiable disease in the United States. The Centers for Disease Control and Prevention (CDC) estimates that 100 to 150 cases of leptospirosis occur annually in the United States, mainly in Puerto Rico, followed by Hawaii. Since most cases are believed to be asymptomatic, cases likely remain unrecognized nationwide and go unreported.

Leptospirosis is a zoonosis primarily associated with occupational or recreational exposure. Working with animals or in rat-infested surroundings poses hazards for veterinarians, dairy workers, swine handlers, slaughterhouse workers, miners, sewer workers, and fish and poultry processors. In the United States, most cases of leptospirosis result from recreational exposures.

In the natural host, leptospires live in the lumen of renal tubules and are excreted in urine. Dogs, rats, and other rodents are the principal animal reservoirs. Hosts acquire infections directly by contact with the urine of carriers or indirectly by contact with bodies of water contaminated with the urine of carriers. Leptospires can survive in neutral or slightly alkaline waters for months. Protective clothing (boots and gloves) should be worn in situations involving possible occupational exposure to leptospires. Control measures include rodent elimination and drainage of contaminated waters. Vaccination of dogs and livestock has been effective in preventing disease but not the initial infection and leptospiuria. Short-term prophylaxis consisting of weekly doxycycline therapy may be appropriate in high-risk groups with expected occupational exposure.

Case check 23.1

Leptospires are present in water and mud contaminated by the urine of reservoir animals. The Case in Point describes significant and repeated exposure risk that should be reported to the primary health care provider on presentation. Otherwise, the initial clinical impression might resemble influenza, especially if presentation occurs during periods of high influenza activity.

Laboratory diagnosis

Specimen collection and handling

Leptospiremia occurs during the acute phase (first week) of the disease, before symptoms are present. Toward the end of the first week as symptoms appear (first 4 to 6 days of illness), blood or cerebrospinal fluid (CSF) should be collected. Optimal recovery occurs if fresh specimens are inoculated directly into laboratory media. Urine can also be collected, but the yield is much higher after the first week of illness, and shedding can occur intermittently for weeks. Ideal submission is whole blood and serum during the first week of acute illness and serum with optional urine during convalescent illness.

Microscopic examination

Although direct demonstration of leptospires in clinical specimens during the first week of the disease by special stains, dark-field microscopy, or phase-contrast microscopy is possible, it is not recommended. Direct demonstration is successful in only a small percentage of cases, and false-positive results may be reported because of the presence of artifacts, especially in urine.

Isolation and identification

Isolation of leptospires is accomplished by direct inoculation of one to two drops of freshly drawn blood or CSF into laboratory media, such as Fletcher semi-solid medium, Stuart liquid medium, or Ellinghausen-McCullough-Johnson-Harris (EMJH) semi-solid medium, and incubation of the media in the dark at room temperature. Several dilutions of urine should be used (undiluted, 1:10, and 1:100) and/or filtered (0.45 μ m) to minimize the effects of inhibitory substances. Tubes are examined weekly for evidence of growth, such as turbidity, haze, or a ring of growth. A drop taken from a few millimeters below the surface is examined by dark-field microscopy for tightly coiled, rapidly motile spirochetes with hooked ends. Serotypes have historically been identified by microscopic agglutination testing using sera of defined reactivity; however, 16S ribosomal nucleic acid sequencing and MALDI-TOF mass spectrometry have been shown to provide accurate species identification.

Polymerase chain reaction (PCR) testing for leptospire DNA in blood, plasma, serum, urine, CSF, and tissue is as sensitive or more so than culture methods. PCR has the advantage of providing a diagnosis in the acute stage, when treatment is most beneficial. Real-time PCR can also quantify the infection burden.

Serologic tests

Most cases of leptospire infection are diagnosed by serology. In patients with leptospiral bacteremia, IgM antibodies are detected within 1 week after onset of disease and may persist in high titers for many months. One month or more after the onset of illness, IgG antibodies can be detected in some patients. A visually read IgM enzyme-linked immunosorbent assay (ImmunoDOT *Leptospira* IgM; GenBio, San Diego, CA) has been approved by the U.S. Food and Drug Administration (FDA) and has demonstrated good performance in cases of acute leptospirosis. A macroscopic slide agglutination test for rapid screening and the gold standard microscopic agglutination test are available for detection of leptospiral antibodies, but both require maintenance of defined serotypes in culture, so their use is typically limited to confirmatory laboratories. Acute and convalescent samples are required to demonstrate a fourfold rise in titer to confirm a diagnosis.

Antimicrobial susceptibility

Susceptibility testing of leptospires is not normally performed in the clinical laboratory; leptospires have been shown to be susceptible in vitro to streptomycin, tetracycline, doxycycline, and the macrolide antimicrobials. For severe disease, intravenous penicillin and ceftriaxone are equally effective. Doxycycline appears to shorten the course of the illness in adults and reduce the incidence of convalescent leptospiruria.

Case check 23.2

At least two deaths occurred in 2009, when confusion with pandemic influenza delayed appropriate antimicrobial therapy in patients with severe leptospirosis. The Case in Point describes two teammates who were taking doxycycline for malaria prophylaxis, which is also effective against many bacterial agents, including *Leptospira*. Adherence to this preventive medicine regimen likely contributed to disease avoidance in these individuals.

Borrelia

General characteristics

The genus *Borrelia* comprises several species of spirochetes that are morphologically similar but have different pathogenic properties and host ranges. Some species cause relapsing fever, whereas several other species cause **Lyme borreliosis**. All pathogenic *Borrelia* are arthropod-borne. Over 20 species are categorized as relapsing fever *Borrelia* that include *Borrelia recurrentis*, *Borrelia hermsii*, and *Borrelia duttonii*. The *B. burgdorferi* sensu lato complex, sometimes simply called *B. burgdorferi*, causes a spectrum of syndromes known as Lyme borreliosis or Lyme disease. Over 20 species belong to this group and include *B. burgdorferi* sensu stricto (often referred to as *B. burgdorferi*), *Borrelia afzelii*, *Borrelia bavariensis*, and *Borrelia bissettii*.

Borreliae are highly flexible organisms ranging in thickness from 0.2 to 0.5 μm and in length from 3 to 20 μm . The spirals range in number from 3 to 10 per cell and are much less tightly coiled than those of the leptospires (Fig. 23.2). Unlike

Fig. 23.2 Appearance of *Borrelia recurrentis* (arrows) in blood (Giemsa stain, $\times 850$).

leptospires and treponemes, borreliae stain easily and can be visualized by bright-field microscopy. Electron microscopy shows the same general features as are seen with the treponemes—long, periplasmic flagella (15 to 20 per cell) coated with sheaths of protoplasm and periplasm.

Borrelia recurrentis and similar borreliae

Virulence factors

As the disease name suggests, relapsing fever is characterized by acute febrile episodes that subside spontaneously but tend to recur over a period of weeks. *Borrelia* spp. responsible for this disease first evade complement by acquiring and displaying suppressive complement regulators, C4b-binding protein, and factor H. The relapses are potentiated by antigenic variation; borreliae systematically change their surface antigens, thereby rendering specific antibody production ineffective in completely clearing the organisms.

Clinical manifestations

After an incubation period of 2 to 15 days, massive spirochetemia develops and remains at varying levels of severity during the entire course of relapsing fever. The infection is accompanied by sudden high temperature, rigors, severe headache, myalgia, arthralgia, and weakness. The febrile period lasts about 3 to 7 days and ends abruptly with the development of an adequate immune response. The disease recurs several days to weeks later, following a less severe but similar course. The febrile periods worsen during the spirochetemia and wane as the immune response clears the bacteria from circulation.

Epidemiology

Relapsing fever can be tickborne (**endemic relapsing fever**) or louseborne (**epidemic relapsing fever**). Tickborne borreliae are transmitted by a large variety of soft ticks of the genus

Ornithodoros except for *Borrelia miyamotoi*, which is believed to be transmitted by the larval hard tick *Ixodes scapularis*. Tickborne borreliae are widely distributed throughout the world, although specific species of borreliae tend to be limited geographically by their vector. Transmission to a vertebrate host takes place via infected saliva during tick attachment.

Louseborne fever, due to *B. recurrentis*, is transmitted via the body louse, *Pediculus humanus*, and humans are the only reservoir. Borreliae infect the hemolymph of the louse. Unlike tickborne disease, transmission of the louseborne disease occurs when infected lice are crushed and scratched into skin, rather than through the bite of an infected arthropod. Relapsing fever is best prevented by controlling exposure to the arthropod vectors. For tickborne relapsing fever, limiting exposure to ticks includes wearing protective clothing, rodent control, and the use of insect repellents. For louseborne relapsing fever, control is best achieved by good personal and public hygiene, especially improvements in measures to avoid overcrowding and in delousing.

Laboratory diagnosis

Microscopic examination

Diagnosis of borreliosis is readily made by observing Giemsa- or Wright-stained smears of peripheral blood taken during the febrile period collected in ethylenediaminetetraacetic acid (EDTA). Relapsing fever is the only spirochetal disease in which the organisms are visible in blood with bright-field microscopy. The appearance of the spirochete among the red blood cells is characteristic (see Fig. 23.2).

Isolation and identification

Whole blood collected in EDTA can also be used for culture and PCR testing, although citrate-treated blood might be superior. Borreliae can be recovered by using Barbour-Stoenner-Kelly medium, but it is rarely attempted. *B. recurrentis*, *Borrelia hermsii*, *Borrelia parkeri*, *Borrelia turicatae*, and *Borrelia hispanica* have been successfully cultivated. Antigenic variation in the spirochetes that cause relapsing fever makes the serodiagnosis of their diseases difficult and impractical with the possible exception of *B. miyamotoi*. Because the borrelia can be readily detected microscopically and by PCR, serologic methods have limited use.

Antimicrobial susceptibility

Borreliae are susceptible to many antimicrobial agents; however, tetracyclines are the drugs of choice because they reduce the relapse rate and rid the CNS of spirochetes. Up to 39% of patients treated with antimicrobial agents experience fever, chills, headache, and myalgia believed to be caused by the sudden release of endotoxin from the spirochetes, a condition referred to as **Jarisch-Herxheimer reaction**.

Borrelia burgdorferi sensu lato

Virulence factors

Bacterial spread may occur depending on the organism's ability to bind plasminogen and urokinase-type plasminogen

activator to its surface. This binding can convert plasminogen to plasmin, which is a potent protease and could facilitate tissue invasion. Binding factor H allows complement evasion and immune system suppression and might explain, in part, why IgM antibody titer does not peak for 3 to 6 weeks. In vitro, the organism can stimulate proinflammatory cytokines, such as tumor necrosis factor and interferons, which can be important in controlling disease but may also contribute to inflammatory manifestations as untreated disease progresses.

Clinical manifestations

Lyme borreliosis is a complex disease that can generally be divided into three stages. Early infection includes two stages, the first of which is localized (stage 1). About 60% to 80% of patients exhibit **erythema migrans (EM)**, the classic skin lesion that is normally found at the site of the tick bite, within 1 week of the tick bite. It begins as a red macule and expands to form large annular erythema with partial central clearing, sometimes described as having a target ("bull's eye") appearance. EM often occurs alone but can be accompanied by fever, fatigue, headache, mild stiff neck, arthralgia, or myalgia. Stage 2 is disseminated early and produces widely variable symptoms that include secondary skin lesions, migratory joint and bone pain, alarming neurologic and cardiac disease, splenomegaly, and severe malaise and fatigue. Late manifestations, or late persistent infections (stage 3), occur mainly in the cardiac, musculoskeletal, and neurologic systems. Arthritis is the most common symptom, occurring weeks to years later.

Epidemiology

Lyme borreliosis is the number one vector-borne disease in the Northern Hemisphere. Organisms are transmitted via the bite of infected *Ixodes* ticks, so most cases occur from June to September, when more people are involved in outdoor activities and ticks are more active. Lyme disease was first described after an outbreak among children in Lyme, Connecticut, in 1975. A total of 23,453 confirmed and 11,492 probable cases were reported in the United States in 2019. The CDC estimates as many as 300,000 Americans contract Lyme borreliosis annually.

At least three genospecies of *B. burgdorferi* sensu lato cause Lyme borreliosis. *B. burgdorferi*, *B. garinii*, and *B. afzelii* are the most common causes of Lyme borreliosis in the United States and Europe. Protective clothing and repellents should be used in areas in which tick exposure is intense. Attached ticks should be removed immediately because pathogen transmission is associated with the length of attachment.

Laboratory diagnosis

Specimen collection and handling

The most common and productive specimen for the laboratory diagnosis of *B. burgdorferi* sensu lato infection is serum for serology. Other tests have too many limitations (e.g., polymerase chain reaction) or have been inadequately validated (e.g., urine and CSF antigen). Large-volume plasma cultures have been shown to be positive in about 50% of adult patients

with erythema migrans. The paucity of bacteria present in clinical samples renders direct microscopy insensitive.

Serologic tests

Diagnosis follows a two-tier approach in which the first step is a sensitive immunofluorescence antibody (IFA), chemiluminescence immunoassay (CLIA), or enzyme immunoassay (EIA) screening that detects IgM and IgG. If the test result is negative, no further testing is needed. Reactive or equivocal results are confirmed with separate IgM and IgG Western immunoblots. If symptoms were present for 30 days or less, the patient is tested for IgM only. Immunoblot confirmation of IgM antibody presence includes reactivity for two of the three following bands: 24, 39, and 41 kilodaltons (kDa). Confirmation of IgG antibody presence is acceptable when 5 of the 10 scored bands are present: 18, 21, 28, 30, 39, 41, 45, 58, 66, and 93 kDa. Because of the low sensitivity of the immunoblot, two-tiered testing is insensitive, particularly in patients with early disease.

To improve sensitivity, in 2019, the FDA cleared several serologic tests that use EIA and CLIA rather than immunoblot in a modified two-test approach. These assays detect antibodies to the proteins C6 and VlsE found in *B. burgdorferi*. If serologic test results are negative and symptoms are consistent with Lyme borreliosis, a convalescent serum should be obtained and tested.

Antimicrobial susceptibility

Early diagnosis and antimicrobial treatment are important for preventing neurologic, cardiac, and joint abnormalities that can occur late in the disease. Doxycycline is the recommended therapy, but macrolides and β -lactams have also been effective in treating early stages of Lyme disease without complications. For refractile or late stages, prolonged treatment with ceftriaxone has been effective. Antimicrobial susceptibility testing is not warranted.

Treponemes

General characteristics

Pathogenic treponemes are thin, spiral organisms about 0.1 to 0.2 μm thick and 6 to 20 μm in length. They are difficult to visualize with a bright-field microscope because they are very thin, but they can be seen easily on dark-field microscopy. The spirals are regular and angular, with 4 to 14 spirals per organism (Fig. 23.3). Three periplasmic flagella are inserted into each end of the cell. The ends are pointed and covered with a sheath. The cells exhibit graceful flexuous movements in liquid.

Clinically significant species

The genus *Treponema* comprises four microorganisms that are pathogenic for humans: *T. pallidum* subsp. *pallidum*, the causative agent of syphilis; *T. pallidum* subsp. *endemicum*, the causative agent of **endemic syphilis**; *T. pallidum* subsp. *pertenue*, the causative agent of **yaws**; and *Treponema carateum*, the

Fig. 23.3 Scanning electron micrograph of *Treponema pallidum*. Two treponemes are shown adjacent to an erythrocyte (Nichols strain, $\times 2500$).

causative agent of **pinta**. The four pathogenic strains exhibit a high degree of DNA homology ($>99\%$) and shared antigens. At least six nonpathogenic species have been identified in the normal microbiota, and they are particularly prominent in the oral cavity. Some of these species, notably *Treponema denticola*, have been linked to the polymicrobial infections gingivitis and periodontitis.

Treponema pallidum subsp. *pallidum*

Virulence factors

Treponema pallidum subsp. *pallidum* can cross intact mucous membranes and the placenta, disseminate throughout the body, and infect almost any organ system. It has also been postulated that antigenic variation of cell surface proteins contributes to the organism's ability to evade host immune response and establish persistent infection.

Clinical manifestations

Treponema pallidum subsp. *pallidum* causes syphilis. The word *syphilis* comes from a poem written in 1530 that described a mythical shepherd named Syphilus, who was afflicted with the disease as punishment for cursing the gods. The poem represented the compendium of knowledge at the time about the disease.

Treponema pallidum subsp. *pallidum* transmission normally occurs during direct sexual contact with an individual who has an active primary or secondary syphilitic lesion. Consequently, the genital organs—the vagina and cervix in females and the penis in males—are the usual sites of inoculation. Syphilis can also be acquired by nongenital contact with a lesion (e.g., on the lip) or transplacental transmission to a fetus, resulting in congenital syphilis. After bacterial invasion through a break in the epidermis or penetration through intact mucous membranes, the natural course of syphilis can be divided into primary, secondary, and tertiary stages based

on clinical manifestations. Co-infection with human immunodeficiency virus (HIV) can result in variation of the natural course of the disease. Furthermore, ulcers caused by syphilis might contribute to the efficiency of HIV transmission in populations with high rates of both infections. Syphilis has a wide variety of clinical manifestations, which gave rise to the name the “great imitator.”

Primary stage of syphilis

The three stages of syphilis are primary, secondary, and tertiary. For reporting and surveillance purposes, the CDC uses the case definition categories primary; secondary; early, nonprimary nonsecondary; and unknown duration or late latent. After inoculation, the spirochetes multiply rapidly and disseminate to local lymph nodes and other organs via the bloodstream. The primary mucocutaneous lesion develops 10 to 90 days after infection and is a result of an inflammatory response to the infection at the site of inoculation. The lesion, known as a chancre, is typically a single erythematous lesion that is nontender but firm, with a clean surface and raised border. The lesion is teeming with treponemes and is extremely infectious. Because the chancre is commonly found on the cervix or vaginal wall and is nontender, the lesion might not be obvious in women. The lesion can also be found in the anal canal of both sexes and remain undetected. The penis is the usual location of chancres in men. No systemic signs or symptoms are evident in the primary stages of the disease.

Secondary stage of syphilis

Approximately 4 to 10 weeks after development of the primary lesion, due to spirochete dissemination, the patient may experience secondary disease, with clinical symptoms of fever, sore throat, generalized lymphadenopathy, headache, lesions of the mucous membranes, and rash. The rash can present as macular, papular, follicular, papulosquamous, or pustular and is unusual in that it can also occur on the palms and soles. All secondary lesions of the skin and mucous membranes are highly infectious. The secondary stage can last for several weeks and can relapse. It might also be mild and go unnoticed by the patient. Relapses of secondary syphilis occur in about 25% of untreated patients.

Tertiary stage of syphilis

Following the secondary stage, patients enter latent syphilis, when clinical manifestations are absent, and the patient is not infectious. Latency within 1 year of infection is referred to as *early latent syphilis*, whereas latency greater than 1 year is *late latent syphilis*. Approximately one third of untreated patients exhibit biological cure, losing serologic reactivity. Another one third remain latent for life but have reactive sera. The remaining one third ultimately develop tertiary or late syphilis, generally decades later. Symptoms of tertiary syphilis include the development of granulomatous lesions (**gummas**) in skin, bones, and the liver (benign tertiary syphilis), degenerative changes in the CNS (neurosyphilis), and syphilitic cardiovascular lesions, particularly aortitis, aneurysms, and aortic valve insufficiency. Patients in the tertiary stage are usually not infectious. In the United States and most developed countries, the tertiary stage of disease is not often seen because most patients are adequately treated with antimicrobial agents before the tertiary stage is reached.

Congenital syphilis

Treponemes can be transmitted from an infected mother to her fetus by crossing the placenta. Congenital syphilis affects many body systems and is therefore severe and mutilating. Early-onset congenital syphilis (onset before 2 years of age) resembles secondary syphilis in adults. It is characterized by mucocutaneous lesions, osteochondritis, anemia, hepatosplenomegaly, and CNS involvement, and it occurs when mothers have early syphilis during pregnancy. Late-onset congenital syphilis, corresponding to tertiary syphilis in adults, results following pregnancies when mothers have chronic, untreated infections. Symptoms of late-onset congenital syphilis occur after 2 years of age but generally are not apparent until the second decade of life. Symptoms include interstitial keratitis, bone and tooth deformities, cranial nerve VIII deafness, neurosyphilis, and other tertiary manifestations.

Epidemiology

Under natural conditions, *Treponema pallidum* subsp. *pallidum* is an exclusively human pathogen. Syphilis was first recognized in Europe at the end of the 15th century, when it reached epidemic proportions. Two theories have been proposed concerning the introduction of syphilis into Europe. One theory suggests that Christopher Columbus's crew brought the disease from the West Indies back to Europe. The second theory suggests that the disease was endemic in Africa and transported to Europe via the migration of armies and civilians. The venereal transmission of syphilis was not recognized until the 18th century. The causative agent of syphilis was not discovered until 1905.

The incidence of syphilis in the United States decreased through the 1990s, and the fewest cases (31,618) since reporting began in 1941 were reached in 2000. However, since 2000, the incidence of the disease has been increasing almost every year, including a 16.4% increase from 2018 to 2020. In 2020, 133,945 cases of all stages of syphilis were reported, which included 41,655 cases of primary and secondary syphilis. From 2016 to 2022, cases of primary and secondary syphilis per 100,000 increased from 15.5 to 20.8 in males and 1.9 to 4.7 in females. Men who have sex with men account for the majority of reported primary and secondary syphilis cases (56.7% in 2019); however, heterosexual syphilis is also increasing. It is up 58.2% among women from 2018 to 2020. An increase in the rate among women corresponds to an increase in the rate of congenital syphilis. The rate of congenital syphilis increased from 8.4 per 100,000 live births in 2012 to 57.3 per 100,000 live births in 2020.

High-risk sexual behavior and co-infection with HIV continue to complicate syphilis control efforts. Educating people about sexually transmitted diseases (STDs), including providing information about the proper use of barrier contraceptives, reporting each case of syphilis to public health authorities for contact investigation, and treating all sexual contacts of persons infected with syphilis are cornerstones of syphilis control efforts. Serologic screening of high-risk populations should be performed, and to avoid congenital syphilis, pregnant women should undergo serologic testing during early and late pregnancy.

Laboratory diagnosis

Specimen collection and handling

Lesions of primary and secondary syphilis typically contain large numbers of spirochetes. The surface of primary or secondary lesions is cleansed with saline and gently abraded with dry, sterile gauze; induction of bleeding should be avoided. Serous transudate is placed onto a slide, diluting it with nonbactericidal saline if the preparation is thick. A coverslip is added, and the slide is transported immediately to a laboratory, where dark-field microscopy is performed. Oral lesions should not be examined because the numerous non-pathogenic spirochetes present in these specimens will lead to misinterpretation. Culture methods are not available, and dark-field microscopy equipment and expertise are uncommon, so serology is the normal basis of diagnosis. Nucleic acid amplification tests are not commonly used, and no FDA-cleared commercial assay is available. Rabbit inoculation tests are considered the gold standard, but they are not practical for routine diagnosis.

Microscopic examination

The organisms are too thin to be observed by bright-field microscopy, so spirochetes are illuminated against a dark background. Dark-field microscopy requires considerable skill and experience; however, demonstration of motile treponemes in material from the chancre is diagnostic for primary syphilis.

Serologic tests

Serology is the primary method used for the laboratory diagnosis of syphilis. Because of the antigenic similarity between the four *Treponema* strains pathogenic for humans, serologic assays cannot distinguish them. Two major types of serologic tests exist: nontreponemal and treponemal. Both have lower sensitivities in the primary stage of syphilis, but approach 100% in the secondary stage. Treponemal tests retain a very high sensitivity in the tertiary stage as well, whereas nontreponemal tests have a lower sensitivity. A co-infection with HIV can result in false-negative serologic test results. Comparisons between CSF and serum antibody responses can be helpful in cases of neurosyphilis. With congenital syphilis, comparing antibody responses in the mother's serum and infant's serum can aid in the diagnosis.

The nontreponemal tests detect reaginic antibodies that develop against lipids released from damaged cells. Although they are biologically nonspecific and known to react with organisms of other diseases and conditions (causing false-positive reactions), the nontreponemal tests are excellent screening tests. The antigen used is a precisely defined cardiolipin-lecithin-cholesterol complex made from bovine hearts. Nontreponemal tests have a lower specificity than treponemal tests. Because a nontreponemal antigen is used in these assays, they are prone to false-positive reactions. All reactive results should be confirmed with a treponemal antigen test.

The two nontreponemal tests widely used today are the **Venereal Disease Research Laboratory (VDRL) test** and the **rapid plasma reagin (RPR) test**. These tests are inexpensive to perform, demonstrate rising and falling reagin titers, and correlate with the clinical status of the patient. For the VDRL test, cardiolipin antigen is mixed with the patient's serum or CSF.

Flocculation is a positive reaction and is observed microscopically. The RPR test is more commonly used; carbon particles are used to visually enhance the reaction and is read on a white card macroscopically. When mixed with a positive serum on a disposable card, the black charcoal particles clump together with the cardiolipin-antibody complexes. The flocculation is easily observed without a microscope. Reactive or weakly reactive sera should undergo titration and be tested with a treponemal test. Recently automated RPR testing has gained FDA clearance. A third nontreponemal antigen test occasionally used is the toluidine red unheated serum test. It is similar to the RPR assay, except toluidine red is substituted for charcoal.

The treponemal tests detect antibodies specific for treponemal antigens. Historically, they have been used to confirm positive nontreponemal test results, although some laboratories use reverse sequence syphilis screening. In this strategy, automated treponemal test-positive serum is retested with a nontreponemal assay and a second treponemal assay. This strategy resulted in higher numbers of false-positive results in five laboratories studied from 2006 to 2010, so the CDC continues to recommend the original approach. Treponemal tests are also helpful in the detection of late-stage infections because the titers remain high and usually do not drop in response to therapy, as with nontreponemal tests. Consequently, treponemal tests are not useful in following therapy or detecting reinfection.

The treponemal antigens used are spirochetes derived from rabbit testicular lesions. Two commonly used treponemal antigen test methods are the *Treponema pallidum*-particulate agglutination (TP-PA) test (Fujirebio America, Fairfield, NJ) and EIAs. The TP-PA test uses gelatin particles sensitized with *T. pallidum* antigens. Agglutination indicates the presence of antitreponemal antibodies. EIA kits are simple to use, commercially available, and comparable with other treponemal tests. They also have the advantage of being semi-automated. The majority use recombinant *T. pallidum* antigens and detect IgG, IgM, or both. The fluorescent treponemal antibody absorption (FTA-ABS) assay uses a fluorescent-labeled antihuman antibody that detects patient antitreponemal antibodies bound to treponema affixed to a commercially prepared slide. Because of subjectivity in reading the samples and the use of expensive fluorescent microscopy, the FTA-ABS test has become less frequently used, and agglutination assays and EIAs are favored.

Neurosyphilis is diagnosed based on clinical and laboratory findings. The VDRL test on CSF has high specificity but low sensitivity. Because of plasma IgG entering the CSF, the FTA-ABS assay on CSF has low specificity but high sensitivity for neurosyphilis. Therefore a negative FTA-ABS assay result is a strong indicator against neurosyphilis, but a negative VDRL test result cannot rule out neurosyphilis.

Rapid immunochromatographic, point-of-care assays using whole blood collected via finger stick have demonstrated sensitivities and specificities like those of *Treponema* antigen tests. Reactive samples need a nontreponemal antigen titer test. The assays employ recombinant *T. pallidum* antigens to detect IgG and IgM. They are useful in STD diagnosis and antenatal clinics. Immunoblot assays are commercially available; some use fractionated *T. pallidum* proteins, and others use recombinant bacterial proteins. The assays can differentiate between IgG and IgM if a separate anti-human immunoglobulin antibody is used.

Antimicrobial susceptibility

Antimicrobial susceptibility testing of *T. pallidum* is not available. Penicillin is the drug of choice for treating patients with syphilis. It is the only proven therapy that has been widely used for patients with neurosyphilis, congenital syphilis, and syphilis during pregnancy. Resistant strains have not developed. Long-acting penicillin, such as benzathine penicillin, is preferred. Alternative regimens for patients who are allergic to penicillin and not pregnant include doxycycline and tetracycline. A typical Jarisch-Herxheimer reaction and exacerbation of cutaneous lesions can occur within hours following treatment.

Other treponemal diseases

Three nonvenereal treponemal diseases—yaws, pinta, and endemic syphilis—occur in different geographic locations. These treponematoses are found in developing countries where hygiene is poor, little clothing is worn, and direct skin contact is common because of overcrowding. All three diseases have primary and secondary stages, but tertiary manifestations are not always seen. All diseases respond well to penicillin or tetracycline. These infections are rarely transmitted by sexual contact, and congenital infections do not occur.

Yaws

Yaws is a spirochetel disease caused by *T. pertenue*. It is endemic in the humid, tropical belt, the tropical regions of Africa, parts of South America, India, Indonesia, and many of the Pacific Islands. It is not seen in the United States. The course of yaws resembles that of syphilis, but the early-stage lesions are elevated, granulomatous nodules (hyperkeratotic papilloma).

Endemic syphilis

Endemic syphilis (“bejel”) is caused by *T. pallidum* subsp. *endemicum* and resembles yaws in clinical manifestations. It is characterized by ulcerative lesions on the oropharyngeal mucosa with split papules in the corners of the mouth. It is found in the Middle East and in the arid, hot areas of the world. The primary and secondary lesions are usually papules that often go unnoticed. They can progress to gummas of the skin, bones, and nasopharynx. Dark-field microscopy is not useful because of normal oral spirochetel biota. Poor hygienic conditions are important in perpetuating these infections. Endemic syphilis is transmitted by direct contact or sharing contaminated eating utensils.

Pinta

Pinta, caused by *T. pallidum* subsp. *carateum*, is found in the tropical regions of Central America and South America. It is acquired by person-to-person contact and is rarely transmitted through sexual intercourse. Lesions begin as scaling, painless papules and are followed by an erythematous rash that becomes hypopigmented with time. The tertiary stage presents with hyperchromic, hypochromic, achromic, or dyschromic plaques. It is unique among the pathogenic treponemes in being limited to the skin.

POINTS TO REMEMBER

- Spirochetes are slender, flexuous, helically shaped, motile bacteria.
- Leptospire are most likely to enter the human host through small breaks in the skin or intact mucosa.
- The incubation period of leptospirosis is usually 10 to 12 days but ranges from 3 to 30 days. The onset of clinical illness is generally abrupt, with nonspecific, influenza-like constitutional symptoms, such as fever, chills, headache, severe myalgia, and malaise.
- The pathogenic borreliae are commonly arthropod-borne (by a tick or louse) and cause relapsing fever and Lyme borreliosis (disease).
- *B. recurrentis* and similar species cause relapsing fever. The relapses are caused by immune evasion, including antigenic variation. During a single infection, borreliae systematically change their surface antigens.
- During the febrile period, diagnosis of relapsing fever is readily made by Giemsa or Wright staining of blood smears. Relapsing fever is the only spirochetel disease in which the organisms are visible in blood with bright-field microscopy.
- Laboratory diagnosis of Lyme borreliosis caused by *B. burgdorferi* sensu lato is accomplished by two-tiered serology. Initial reactive or equivocal EIA results are confirmed with an immunoblot or secondary EIA.
- Serologic assays are the most common method for diagnosing syphilis. However, these assays cannot distinguish among the four pathogenic treponemes.
- Among adults, treponemes are transmitted by close, intimate contact. Treponemes can cross the placenta and be transmitted from an infected mother to her fetus. Congenital syphilis affects many body systems and is therefore severe and mutilating. All pregnant women should have serologic testing for syphilis early in pregnancy.

LEARNING ASSESSMENT QUESTIONS

1. What are the general characteristics of spirochetes?
 - a. Slender (0.1 to 0.5 μ m wide)
 - b. Helix-shaped with one or more complete turns in the helix
 - c. Flexible cell wall around which several fibrils are wound
 - d. All of the above
2. Which risk factor is not associated with *Borrelia* spp. endemic relapsing fever?
 - a. Geographic location
 - b. Louse infestation
 - c. Outdoor exposure
 - d. History of tick bites
3. Which tickborne spirochete is associated with a rash or skin lesion?
 - a. *Borrelia burgdorferi* sensu lato
 - b. *Treponema pallidum* subsp. *carateum*
 - c. *Borrelia recurrentis*
 - d. *Leptospira interrogans* sensu lato
4. What is the significance on infectious disease transmission of finding partially engorged ticks attached to skin?
 - a. Pathogen transmission is more probable the longer the vector is attached.
 - b. Pathogen transmission does not occur unless fully engorged.

- c. More than one tick is required for disease transmission.
 - d. There is no significance.
5. What is the typical test of choice for the laboratory diagnosis of relapsing fever?
 - a. Serology
 - b. Dark-field microscopy
 - c. Peripheral blood smear stained with Giemsa stain
 - d. Culture in Ellinghausen-McCullough-Johnson-Harris (EMJH) media
6. A nonreactive result is obtained on a nontreponemal assay performed on serum from a patient suspected of having syphilis. What should be the next step?
 - a. Repeat the nontreponemal assay to confirm the nonreactive result.
 - b. Perform a treponemal assay to confirm the nonreactive result.
 - c. Request a second specimen in 1 week.
 - d. Report the result as nonreactive.
7. Which stage of syphilis is characterized by neurologic symptoms and a reactive treponemal antigen test?
 - a. Primary
 - b. Secondary
 - c. Tertiary
 - d. Latent
8. Where are the most cases of leptospiroses contracted within the United States and its territories?
 - a. Florida
 - b. California
 - c. Virginia
 - d. Puerto Rico
9. Leptospira are typically transmitted from natural hosts, dogs, and rodents to humans via which type of contact?
 - a. Animal bites
 - b. Insect vectors
 - c. Contact with animal feces
 - d. Contact with water contaminated with urine
10. Which of the following are a treponemal antigen serologic test for syphilis? *Select all that apply.*
 - a. VDRL
 - b. FTA
 - c. RPR
 - d. TPPA

Chlamydia, *Rickettsia*, and similar organisms

Donald C. Lehman

CHAPTER OUTLINE

Chlamydiaceae, 544

General characteristics, 544

Chlamydia trachomatis, 544

Chlamydia pneumoniae, 547

Chlamydia psittaci, 548

Rickettsiaceae and similar organisms, 552

Rickettsia, 552

Orientia, 554

Anaplasmataceae, 555

Coxiella, 556

Bibliography, 557

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. List the members of the family Chlamydiaceae.
2. Discuss the unique growth cycle of *Chlamydia*, describing elementary and reticulate bodies.
3. Describe how the *Chlamydia* and *Rickettsia* differ from other bacteria and viruses.
4. Discuss the most important human diseases caused by the *Chlamydia*, *Rickettsia*, and similar microorganisms.
5. Describe the modes of transmission for each species of *Chlamydia*, *Rickettsia*, and similar microorganisms.
6. Compare the epidemiology and pathogenesis of the serovars of *Chlamydia trachomatis*.
7. Evaluate the available assays for the laboratory diagnosis of *C. trachomatis* and *C. pneumoniae* infections.
8. Discuss the problems with serologic cross-reactivity among the rickettsial species.
9. For the following human rickettsial diseases, compare the causative agents and mode of transmission to humans:
 - Louseborne typhus
 - Rocky Mountain spotted fever
 - Scrub typhus

10. Compare the characteristics and pathogenesis of *Ehrlichia* spp. and *Anaplasma phagocytophilum*.
11. Compare the characteristics of the *Rickettsia* and *Coxiella* and the diseases they cause.
12. Justify the use of serologic assays to diagnose ehrlichiosis and anaplasmosis.

KEY TERMS

Brill-Zinsser disease

Bubo

Elementary body (EB)

Human granulocytic anaplasmosis (HGA)

Human monocytic ehrlichiosis (HME)

Lymphogranuloma venereum (LGV)

Morulae

Pelvic inflammatory disease (PID)

Reiter syndrome

Reticulate body (RB)

Trachoma

Case in point

A 7-day-old female neonate was brought by her grandmother to the emergency department of a large city hospital. She had been discharged 3 days after birth, with the last nursing note indicating that the child was “fussy.” The newborn arrived at the emergency department with a temperature of 39°C, loss of appetite, profuse yellow discharge from the right eye, and general irritability. Medical history revealed the mother to be a 17-year-old intravenous drug abuser with no prenatal care, who had a vaginal delivery in the parking lot of a local hospital. Eye discharge and cell scrapings were cultured. Routine bacterial cultures were negative; however, a rapid nucleic acid amplification test (NAAT) was diagnostic.

Issues to consider

After reading the patient's case history, consider:

- The various organisms that can be recovered from exudative material from newborns
- The clinical infections and disease spectrum associated with these organisms

- How these organisms are transmitted and the risk factors associated with the diseases produced
- The appropriate methods of laboratory diagnosis

This chapter covers obligate intracellular organisms that are either extremely difficult to culture or are nonculturable. Molecular biology assays are used to detect the more commonly seen human pathogens among this group. Their very small size and obligate intracellular parasitism are major characteristics that differentiate the organisms of the genera *Chlamydia*, *Rickettsia*, *Orientia*, *Anaplasma*, and *Ehrlichia* from other bacterial species.

The genus *Chlamydia* is the only genus in the family Chlamydiaceae. A proposal to add the genus *Chlamydophila* was ultimately rejected. The creation of a second genus was somewhat controversial. Therefore readers may find both taxonomic classifications in published literature. Members of the family share characteristics (Table 24.1) and have a unique life cycle. Within the genus *Chlamydia*, four species were previously recognized: *C. pecorum*, *C. pneumoniae*, *C. psittaci*, and *C. trachomatis*. Based on analysis of 16S and 23S ribosomal ribonucleic acid (rRNA) gene sequences, the taxonomic classification was revised. The genus *Chlamydia* consists of the human pathogens *C. trachomatis*, *C. pneumoniae*, and *C. psittaci*. Other named species of *Chlamydia* exist, but they are rarely isolated from humans.

The term *rickettsiae* can specifically refer to the genus *Rickettsia*, or it can refer to a group of organisms included in the order Rickettsiales. There has been significant reorganization in the order Rickettsiales in recent years. The order includes the families Rickettsiaceae and Anaplasmataceae. The family Rickettsiaceae includes the genera *Rickettsia* and *Orientia*. The family Anaplasmataceae includes the genera *Ehrlichia*, *Anaplasma*, *Neorickettsia*, and *Wolbachia*. As a result of this reorganization, *Coxiella* has been removed from the family Rickettsiaceae and placed into the family Coxiellaceae.

Chlamydiaceae

General characteristics

Currently, there are about 15 *Chlamydia* species. As shown in Table 24.2, initial differentiation of the *Chlamydia* spp. associated with human disease was based on selected characteristics of the growth cycle, susceptibility to sulfa drugs, accumulation of glycogen in inclusions, and deoxyribonucleic acid (DNA) relatedness. Table 24.2 also lists additional properties of the Chlamydiaceae species that have helped further differentiate the three human species based on natural host, major diseases, and number of antigenic variants (i.e., serovars).

Chlamydiae are deficient in energy metabolism and are therefore obligate intracellular parasites. Historically, it was believed that the chlamydiae were strictly energy parasites. However, gene sequencing identified the presence of enzymes for the metabolism of glucose 6-phosphate to pyruvate via glycolysis, allowing the bacteria to generate adenosine triphosphate (ATP) via substrate-level phosphorylation. The bacteria depend on the phosphorylated sugar, D-glucose 6-phosphate, from the host cell. Although

chlamydiae do take up ATP from the host cell, they are able to produce their own ATP from D-glucose 6-phosphate also taken from the host cell. The tricarboxylic acid (Krebs) cycle is incomplete in all Chlamydiaceae, and they are unable to synthesize most amino acids, cofactors, and purine and pyrimidine nucleotides.

Their unique growth cycle involves two distinct forms, an **elementary body (EB)**, which is infectious, and a **reticulate body (RB)**, which is noninfectious. The EB has sporelike features in that they are resistant to environmental physical stress. It was believed that EBs are inert; however, recent studies have demonstrated some metabolic activity without cellular division. The growth cycle (Fig. 24.1) begins when the small EB infects the host cell by inducing energy-requiring active phagocytosis where they remain within membrane-bound phagosome. The bacteria prevent interaction of the phagosome with endosomes.

In vivo, host cells are primarily the nonciliated, columnar, or transitional epithelial cells that line the conjunctiva, respiratory tract, urogenital tract, and rectum. During the next 8 hours after cellular penetration, they organize into larger, less dense RBs, which divert the host cell's synthesizing functions to their metabolic needs and begin to multiply by binary fission. About 24 hours after infection, the dividing organisms begin reorganizing into infective EBs. At about 30 hours, multiplication ceases, and by 35 to 40 hours, the disrupted host cell dies, releasing new EBs (Fig. 24.2) that can infect other host cells, continuing the cycle.

The EB has an outer membrane like that of many gram-negative bacteria. The most prominent component of this membrane is the major outer membrane protein (MOMP). The MOMP is a transmembrane protein that contains both species-specific and subspecies-specific epitopes that can be defined by monoclonal antibodies. The *Chlamydia* outer membrane also contains lipopolysaccharide (LPS). This extractable LPS is the primary antigen detectable in genus-specific serologic assays.

Chlamydia trachomatis

C. trachomatis has been divided into two biovars: trachoma and lymphogranuloma venereum. In addition, characterization of the MOMP has separated *C. trachomatis* into 20 serovariants, or serovars (Table 24.3). The trachoma biovar includes serovars A to K. Serovars A, B, Ba, and C are associated with the severe eye infection trachoma, whereas serovars D to K, Da, Ia, and Ja are associated with inclusion conjunctivitis, a milder eye infection, and urogenital infections. Serovars L1, L2, L2a, L2b, and L3 are associated with **lymphogranuloma venereum (LGV)**, an invasive urogenital tract disease. The serovars L are referred to as the biotype LGV, while serovars A to K are called the *trachoma* biovar.

Most *Chlamydia* species carry a plasmid. Analysis of the genus-wide plasmid produced three lineages and indicates that all three evolved from a common ancestor. The plasmids' high level of conservation across the genus implies a strong evolutionary selection for their retention. The plasmid found in *C. trachomatis* is important for virulence and establishing persistent infections, but its role in pathogenesis is unknown. NAATs, such as polymerase chain reaction (PCR), are currently the most commonly used methods to diagnose these infections.

Table 24.1 Comparative properties of microorganisms

Characteristic	Infectious agents				
	Typical bacteria	Chlamydiae	Rickettsiae	Mycoplasmas	Viruses
DNA and RNA	+	+	+	+	–
Obligate intracellular parasites	–	+	+	–	+
Peptidoglycan in cell wall	+	+	–	–	–

Major human diseases	Sexually transmitted diseases Trachoma Lymphogranuloma venereum	Pneumonia Pharyngitis Bronchitis	Pneumonia FUO

+, Characteristic is present; –, characteristic is absent; FUO, fever of unknown origin.

Clinical infections

Trachoma

C. trachomatis causes the chronic eye infection trachoma (Fig. 24.3). Although cataracts is the leading cause of blindness worldwide, an estimated 1.2 million people currently have blindness caused by trachoma. An estimated 200 million people live in trachoma-endemic areas. In 1996, the World Health Organization began the Alliance for the Global Elimination of Trachoma by the year 2020 (GET2020). Despite widespread success, trachoma is still the number-one cause of preventable blindness in the world.

Trachoma is associated with serotypes A, B, Ba, and C. These serovars are most frequently found near the equator and in climates with high temperature and high humidity; they are not commonly seen in the United States. These serovars produce a chronic infection that, if left untreated, generally results in blindness in adults. Prevention and treatment include antimicrobial therapy, facial cleanliness, environmental improvement, and a simple surgical procedure on the eyelid. Trachoma is a chronic disease that begins as follicular conjunctivitis. The chronic inflammation causes the eyelid to turn inward, which results in continual abrasion to the cornea from the eyelashes. The condition results in scarring and ulceration of the cornea. This can result in secondary bacterial infection and blindness.

Lymphogranuloma venereum

C. trachomatis serovars L1, L2, L2a, L2b, and L3 cause LGV, a sexually transmitted disease (STD); these serovars are more invasive than the others. Patients with LGV present with inguinal and anorectal symptoms (Fig. 24.4). Following an incubation period of 1 to 4 weeks, patients develop a small papule or lesion at the site of infection (e.g., penis, vaginal wall, cervix). This is followed by swelling of the regional lymph nodes. The serovars causing LGV can survive inside mononuclear cells, and the bacteria enter the lymph nodes and produce a strong inflammatory response that often results in fluctuant **bubo** formation and subsequent rupture of the lymph node. Proctitis is common in women because of lymphatic spread of bacteria from the vagina or cervix. Men can develop proctitis as a result of anal-receptive intercourse or lymphatic spread from the urethra. The LGV serovars have also been linked to Parinaud oculoglandular conjunctivitis.

Because LGV is no longer a reportable disease, its prevalence in the United States is unknown; however, it is believed to be uncommon. LGV is usually seen in immigrants and travelers returning from countries in which the disease is endemic, typically the tropics and subtropics. Studies have shown that men who have sex with men and individuals who are infected with the human immunodeficiency virus are disproportionately affected with LGV.

Fig. 24.1 Life cycle of *Chlamydia*.

Fig. 24.2 Elementary bodies and cells in a *Chlamydia trachomatis*-positive direct specimen (×400). (Courtesy Syva Microtrak, Palo Alto, CA.)

Other urogenital diseases

C. trachomatis causes urogenital infections in both women and men. Serovars D to K are associated with these clinical infections, which can be persistent and subclinical as well as acute. The same serovars can produce conjunctivitis in both males and females. Typical clinical manifestations of urogenital infection include cervicitis, endometritis, salpingitis, proctitis in women and

Table 24.3 Human diseases caused by <i>Chlamydiaceae</i> species			
Species	Serovars ^a	Disease	Host
<i>Chlamydia trachomatis</i>	A, B, Ba, C	Trachoma	Humans

^aPredominant serovars associated with disease.

Fig. 24.3 Conjunctival scarring and hyperemic blindness caused by *Chlamydia trachomatis* in ocular infections.

Fig. 24.4 Inguinal swelling and lymphatic drainage caused by *Chlamydia trachomatis* serovars L_1 , L_{2a} , L_{2b} , or L_3 (i.e., lymphogranuloma venereum).

nongonococcal urethritis (NGU), epididymitis, prostatitis, and proctitis in men. **Pelvic inflammatory disease (PID)** and perihepatitis are not uncommon complications in women. Between 45% and 68% of female partners of men with *Chlamydia*-positive NGU yield chlamydial isolates from the cervix. Approximately 50% of current male partners of women with a cervical chlamydial infection are also infected. Most infected women (up to 80%) and some men (approximately 25%) remain asymptomatic, which facilitates spread of bacteria through unprotected sexual contact. Salpingitis can lead to scarring and dysfunction of the oviductal transport system, resulting in infertility or ectopic pregnancy. In the United States, this is a significant cause of sterility. **Reiter syndrome** (urethritis, conjunctivitis, polyarthritides, and mucocutaneous lesions), also known as *reactive arthritis*, is believed to be caused by *C. trachomatis*.

C. trachomatis is the most common sexually transmitted bacterial pathogen and the most common notifiable disease in the United States. In 2020, a total of 1,579,885 cases were reported, a decrease of 13% compared to 2019. This follows an increase of 19.4% from 2014 to 2018. More worrisome is that many infections remain undiagnosed, and the Centers for Disease Control and Prevention (CDC) estimates that 2 million to 3 million new cases occur annually in the United States. It was reported in 2020 that 84% of all reported chlamydia

Table 24.4 Inclusion conjunctivitis in the neonate caused by *Chlamydia trachomatis*

Characteristic	Comments
Incubation period	4–5 days
Signs	Edematous eyelids
Discharge	Copious, yellow
Course	Untreated, weeks to months
Complications	Corneal panus formation, conjunctival scarring

cases in females were among those 15 to 29 years of age. For males, 71% of cases occurred in the same age group. Genital warts, caused by human papillomavirus, is a more common STD in the United States.

Chlamydial infection in the newborn

Because of the high incidence of chlamydia infection in women of childbearing age, health professionals have suggested routine screening of women who are pregnant for colonization. Newborns can be infected with *C. trachomatis* while traveling through an infected birth canal. Chlamydial infection in a newborn delivered by cesarean section is rare, and infection from seronegative mothers has not been reported. Newborns with chlamydial infection can experience conjunctivitis, nasopharyngeal infections, and pneumonia. [Table 24.4](#) shows selected features associated with neonatal inclusion conjunctivitis. The portal of entry is ocular or aspiration, with oropharynx colonization being a necessary event before infection. Infants born in the United States receive prophylactic eye drops, generally erythromycin, to prevent eye infections by *C. trachomatis* and *Neisseria gonorrhoeae*.

Clinically, it is believed that pneumonia in infants younger than 6 months of age is associated with *C. trachomatis*, unless proven otherwise. This pneumonia also can occur as a mixed infection with gonococcus and cytomegalovirus and other viruses. The incubation period for *C. trachomatis* pneumonia is variable, but symptoms generally appear 2 to 3 weeks after birth. Studies have suggested that some cases of sudden infant death syndrome might be caused by *C. trachomatis*.

Case check 24.1

In the Case in Point, the neonate presented with conjunctivitis and symptoms of pneumonia. The signs and symptoms along with the neonate's history are suggestive of *C. trachomatis* infection.

Chlamydia pneumoniae

Chlamydia pneumoniae, formerly known as *Chlamydia* sp. strain TWAR, was originally identified in 1965 from a conjunctival culture of a child (TW) enrolled in a Taiwan trachoma vaccine study. In 1983 at the University of Washington, a similar organism was isolated in HeLa cells from a pharyngeal specimen of a college student (AR). To date, only a single *C. pneumoniae* serovar has been found.

C. pneumoniae is recognized as an important respiratory pathogen thought to be transmitted in human secretions. It is known to be a cause of sinusitis, pharyngitis, acute respiratory

Table 24.5 Summary of key epidemiologic and clinical features of *Chlamydia pneumoniae* infections

Epidemiologic	Clinical
Almost no antibody detectable before 5 years of age	Estimated to account for approximately 6%–10% of outpatient and hospitalized pneumonia; 90% of infections are asymptomatic or mildly symptomatic
Antibodies present in >50% of adults	Biphasic illness—prolonged sore throat, croup-like hoarseness, followed by lower respiratory tract (flulike) symptoms
Attack rate highest between 6 and ≈25 years of age, often focusing on college-age students	Pneumonia and bronchitis, rarely accompanied by sinusitis
No seasonal incidence; epidemics have been reported every 4–6 years	Fever relatively uncommon
Reinfection common	Chest radiograph shows isolated pneumonitis
	One in nine infections results in pneumonia.
	Sarcoidosis, cardiovascular relationships (?)

Table 24.6 Evaluating for *Chlamydia pneumoniae*

Population or situation	Evaluation methods	Comments
Pneumonias requiring hospitalization (age 6–20 years)	<i>C. pneumoniae</i> -specific IgM and IgG: acute and convalescent, use MIF IgM, single visit	12% antibody prevalence
Pharyngitis in college students		9% antibody prevalence
Retrospective, undiagnosed outbreaks in young adults, college students, or military trainees	CF or MIF, IgG specific	
Serious pneumonia, undiagnosed; clinically presents like <i>Mycoplasma pneumoniae</i>	<i>C. pneumoniae</i> -specific IgM and IgG by MIF	If negative, rather than perform cultures for similar respiratory pathogens (i.e., <i>Mycoplasma pneumoniae</i>), reevaluate the patient to determine whether additional testing is necessary

CF, Complement fixation; IgG, immunoglobulin G; IgM, immunoglobulin M; MIF, microimmunofluorescence.

disease, bronchitis, and pneumonia. It also has been isolated from patients with otitis media with effusion, pneumonia with pleural effusion, and aseptic pharyngitis. *C. pneumoniae* can cause a mild atypical pneumonia resembling pneumonia caused by *Mycoplasma pneumoniae*. Probably 90% of infections are asymptomatic or mildly symptomatic, causing a chronic cough and malaise. Hospitalization is rare. Unlike viral respiratory diseases, there seems to be no seasonal incidence. Reinfection with *C. pneumoniae* appears to be common and can be milder or more severe than the initial infection. The epidemiologic and clinical features of *C. pneumoniae* are listed in Table 24.5. The mode of transmission, incubation period, and infectiousness of *C. pneumoniae* infections are still largely unknown. No animal reservoir or vector is known. Table 24.6 summarizes situations and/or populations at risk that would benefit from the detection of *C. pneumoniae*, usually by serologic methods.

The prevalence of *C. pneumoniae* infection is controversial, but infections are thought to be common, with an estimated 200,000 cases per year in the United States. *C. pneumoniae* is regarded as the third most common cause of infectious respiratory disease. It accounts for up to 10% to 15% of community-acquired cases of pneumonia. However, a meta-analysis of 63 research articles published between 1995 and 2019 indicated that *C. pneumoniae* caused a low number of community-acquired pneumonia cases. In PCR studies, the rate of identification of *C. pneumoniae* as a possible pathogen ranged from 0% to 8.95%. Supporting the fact that many infections are asymptomatic or mild, antibodies were demonstrated in 50% to 70% of adults in some populations. It is thought that the attack rate is highest between 6 and 20 years of age, with a particular emphasis in college-age students. Outbreaks have been reported in schools, prisons, and the military.

The clinical picture in college-age students, although it may vary, has a biphasic clinical course. *C. pneumoniae* infection results in prolonged sore throat (5–7 days) and hoarseness, followed by flulike lower respiratory tract symptoms (8–15 days). Because of its striking clinical similarity to bacterial pharyngitis, the result of a streptococcal antigen test often is thought to produce false-negative results. The second phase of the biphasic illness often results in pneumonia (approximately one in nine infections) and bronchitis but is rarely accompanied by sinusitis. Fever is relatively uncommon, and x-rays show isolated pneumonitis.

C. pneumoniae has been implicated as a possible factor in asthma and cardiovascular disease. The organism has been detected in atherosclerotic tissue by culture and NAATs; however, its possible pathogenic role remains under investigation. Association of this organism with other vascular diseases, such as abdominal aortic aneurysm, has also been considered.

Chlamydia psittaci

Chlamydia psittaci is the cause of psittacosis (*psittakos* is the Greek word for parrot) among psittacine birds, also known as *ornithosis* or *parrot fever*. Many avian species can harbor *C. psittaci*. DNA sequencing led to the naming of new species that were formerly considered *C. psittaci*. They include *Chlamydia felis*, *Chlamydia caviae*, and *Chlamydia abortus*.

Inhalation of *C. psittaci* bacteria following contact with poultry is the greatest risk for infection. Person-to-person spread seems unlikely. The bacteria enter the respiratory tract and can spread to the reticuloendothelial cells of the liver and spleen. A lymphocytic inflammatory response occurs in the alveolar and interstitial spaces that can produce edema, necrosis, and bleeding in the lungs. Human infection can

Table 24.7 Appropriate *Chlamydia trachomatis* assays for selected patient populations

Assay	Patient population								Legal applicability (rape or child abuse?)	Test of cure
	Prenatal		Newborn			Clinics ^a

MIF	NA	B	—	—	A (IgM)	B	B	No	No	

A, Most useful, stands alone; B, probable, but needs verification or complementary assay recognizing different *Chlamydia trachomatis* macromolecules, i.e., lipopolysaccharide (enzyme immunoassay [EIA]) versus major outer membrane protein (direct fluorescent antibody [DFA]) or competition assay for DNA probes; CFI, complement fixation; IgM, immunoglobulin M; IUO, investigational use only; LGV, lymphogranuloma venereum; MIF, microimmunofluorescence; NA, not available; OIA, optical immunoassay; PCR, polymerase chain reaction; SDA, strand displacement amplification; TMA, transcription-mediated amplification.

^aA low-risk population is defined as one with a less than 5% incidence, such as in an obstetrics-gynecology or family practice patient group (e.g., birth control, annual gynecologic examination). A high-risk population is defined as one with a more than 10% incidence, such as those in sexually transmitted disease clinics, those in university or college student health centers, and emergency department patients.

be asymptomatic or mild, or it can present as a severe, even life-threatening pneumonia. Symptoms include fever, chills, muscle aches, and severe headache. In the United States, fewer than 50 cases of *C. psittaci* are reported annually, although the number of cases might be underreported because infection can be mild. Most cases are associated with occupational exposure by breeding pet birds and working in poultry processing plants, particularly turkey processing plants.

Laboratory diagnosis of chlamydial diseases

There are numerous methods for the laboratory diagnosis of *C. trachomatis* that differ in sensitivity, specificity, negative predictive value (NPV), and positive predictive value (PPV). Table 24.7 identifies the situations in which the tests may be most applicable and identifies the population groups at greatest risk. Table 24.8 provides the predictive values for isolation, detection, and identification methods. The most appropriate tests or combinations of assays used depend on the following factors:

- Knowledge of the population at risk
- Capability and facilities available for testing
- Cost of assays
- Ability to batch specimen types
- Experience of the laboratory scientist

Prevalence in the population to be tested is an important criterion in determining which method or combination of methods should be used. For any assay, the PPV increases (assuming optimal technical conditions) when the prevalence of the disease in the population is high. The type of specimen

selected for laboratory processing depends on the symptoms of the patient and the clinical presentation. Regardless of the source, however, the specimen should consist of infected epithelial cells and not exudate. First morning voided urine for men and vaginal swab specimens for women are excellent for detecting infection. Urine is an acceptable alternative for women.

Dacron, cotton, and calcium alginate swabs can be used, but it should be noted that toxicity has been associated with different lots of each, which is a concern if culture is attempted. Furthermore, it is important to remember that swabs with plastic or metal shafts are superior to those with wooden shafts, which are toxic to cells. Table 24.9 lists the optimal specimens for detection of *Chlamydia* spp. in patients with a variety of clinical manifestations. Specimens for culture must be placed into a transport medium, such as sucrose phosphate glutamate buffer, and transported to the laboratory at 4°C or below within 24 hours. Because molecular biology assays are widely available, cultures are rarely attempted in clinical laboratories.

Specimens collected for the detection of *C. pneumoniae* include nasopharyngeal and throat swabs, sputum, bronchial lavage fluid, and tracheal aspirates (see Table 24.9). *C. psittaci* is most often diagnosed based on the clinical presentation, history of bird exposure, and serologic assays.

Direct microscopic examination

Direct specimen examination by cytologic methods primarily involves trachoma and inclusion conjunctivitis (Fig. 24.5). This method is technically demanding and influenced by the quality of the specimen and expertise of the laboratory scientist. Although this method is difficult to use with

Table 24.8 Detection capabilities of various methods for *Chlamydia trachomatis*

	SENS ^a (%)	SPEC ^a (%)	PPV ^a (%)	NPV ^a (%)	Specimen site				False ±	Reported cross-reactivity	Comments
					Cervical- urethral	Rectal	Urine	Eye			
Culture	50–85	100	73–98	90–100	+	+	+	+	False –	None	Labor-intensive gold standard for specificity
Nonculture, nonamplified											
DFA	75–85	92–98	73–98	95–99	+	+	–	+	False ±	Staphylococci	Screen only; experience in FA needed
EIA	72–95	90–99	45–92	95–99	+	–	LA	LA	False ±	Streptococci, GC, <i>Acinetobacter</i>	Verify with com- plementary assay

^aRange—low to high prevalence as described in the text.

DFA, Direct fluorescent antibody; EIA, enzyme immunoassay; FA, fluorescent antibody; LA, limited availability; NPV, negative predictive value; PCR, polymerase chain reaction; PPV, positive predictive value; SDA, strand displacement amplification; SENS, sensitivity; SPEC, specificity; TMA, transcription-mediated amplification.

Table 24.9 Appropriate specimens for detection of Chlamydial infections

Clinical manifestation, site of infection	Specimen site, type	Comments
Inclusion conjunctivitis and trachoma	Conjunctival swab, scraping with spatula	Specimen collection in neonates is difficult
Urethritis	Urethral swab	In males, insert swab >4 cm; do not use discharge
Epididymitis	Epididymis aspirate	
Cervicitis	Endocervical swab	Remove exudate first
Salpingitis	Fallopian tube (lumen) or biopsy	
Sexually transmitted disease, result clarification	Rectal, vaginal swabs	May be used for supplemental information and in clarifying previous isolates or diagnostic dilemmas
Sexually transmitted disease, male sex partner	Urine	Noninvasive diagnostic procedure; EIA antigen detection is 80% accurate, PCR is 98% accurate
Lymphogranuloma venereum	Bubo or lymph node aspirate	
Infant pneumonia	Throat swab, nasopharyngeal aspirate, or lung tissue	
<i>Chlamydia pneumoniae</i> pneumonia or pharyngitis	Throat washing, throat swab, sputum, bronchial lavage fluid, lung tissue	Tissue culture isolation and direct immunofluorescence are relatively new and need further evaluation
Psittacosis	Sputum, bronchial lavage fluid, pleural fluid, lung tissue	

EIA, Enzyme immunoassay; PCR, polymerase chain reaction.

large numbers of specimens, it does offer rapidity in selected cases, particularly in detecting ocular infection in newborns.

Direct fluorescent antibody (DFA) testing should not be used routinely for genital tract specimens. It is, however, appropriate for rapid diagnosis of inclusion conjunctivitis in infants and sometimes adults. The assay requires an experienced microscopist and is labor-intensive. The sensitivity is 75% to 85%, and cross-reactivity to other bacteria has been reported. The assay

was developed in the 1980s and uses a species-specific epitope on the MOMP. Direct specimen examination offers one additional important advantage—it allows immediate quality control of the specimen, revealing whether columnar epithelial cells are present. Fig. 24.6 shows inclusion bodies demonstrated by direct examination of cytologic stains of endocervical smears. An indirect fluorescent antibody method has been reported for detecting *C. pneumoniae* in respiratory secretions; the antibody

reacts with the MOMP (Fig. 24.7). This same antibody can be used to identify infected cell culture monolayers.

Immunoassays

Direct enzyme immunoassays (EIAs) use monoclonal or polyclonal antibodies directed against the chlamydial LPS. Several commercial kits are available for *C. trachomatis*. They can screen large numbers of specimens, obtain objective results, obtain results in 3 to 5 hours, and use various specimen types. However, none of them equals the sensitivity of culture or NAATs, and many are prone to false-positive results. Because of these limitations, the CDC considers EIAs substandard for the detection of *C. trachomatis*, and they are not recommended for diagnosis.

Cell culture

Until the development of NAATs, chlamydial cell culture was considered the gold standard for detecting *C. trachomatis* infection; however, the usefulness of cell culture has been limited because of the inherent technical complexity, time and specimen handling requirements, expense, biosafety hazard

concerns, and labile nature of the organisms. Even under the most stringent and optimal conditions, isolation of chlamydiae is only approximately 80% sensitive. *C. pneumoniae* can also be recovered in cell cultures. Isolation of *C. psittaci* in culture, although diagnostic, is difficult, dangerous, and not routinely used or recommended.

Fluorescein-labeled monoclonal antibodies can be used to detect the chlamydial inclusions found associated with infected cell lines. Several fluorescent antibodies are available commercially. Some laboratories use species-specific monoclonal antibodies that bind to the MOMP, whereas others prefer the family-specific antibody, which binds to an LPS component. Monoclonal antibodies against the MOMP are reported to offer the brightest fluorescence, with consistent bacterial morphology and less nonspecific staining than monoclonal antibodies against the LPS. Iodine or Giemsa stain can be used, but these methods are less sensitive and specific and are no longer recommended (see Fig. 24.7).

Nucleic acid hybridization and amplification assays

Because of high sensitivity and specificity, the NAATs are the preferred method for the diagnosis of *C. trachomatis* infection. NAATs detect 30% to 50% more *C. trachomatis* infections than culture or earlier nonculture assays. NAATs offer several advantages, including U.S. Food and Drug Administration (FDA) approval to detect *C. trachomatis* in endocervical swabs from women, urethral swabs from men, and urine from men and women. These assays can have the added advantage of detecting two STDs in one sample—gonorrhea and *C. trachomatis* infection. The sensitivity, specificity, NPV, and PPV are higher than those reported for EIAs and cultures. Results can be obtained quickly, and testing is less technically demanding than culture. However, currently no NAAT has been approved for use on conjunctival, oropharyngeal, or rectal specimens. The assays also cannot distinguish LGV strains from other *C. trachomatis* serotypes (A to K).

Five NAATs are currently licensed for use in the United States for the detection of *C. trachomatis* in clinical specimens: the PCR-based Cobas CT/NG (Roche Molecular Systems, Indianapolis, IN); the GenXpert CT/NG (Cepheid, Sunnyvale, CA); the Abbott RealTime m2000 CT/NG (Abbott Molecular, Des Plaines, IL); the APTIMA Combo 2 CT/GC transcription-mediated amplification assay (Hologic, San Diego, CA);

Fig. 24.5 Inclusion body from an ocular swab from a 7-day-old newborn who was discharged but then readmitted with fever, weight loss, lack of eating, and “fussiness.” At 3 days after delivery, *Neisseria gonorrhoeae* was isolated from the ocular discharge, although the patient had been given silver nitrate eye drops. Eye cultures confirmed the presence of *Chlamydia trachomatis* (Giemsa stain, $\times 600$).

Fig. 24.6 Cytologic examination of endocervical specimens demonstrating inclusion bodies consistent with *Chlamydia trachomatis* (Papanicolaou stain; **A**, $\times 600$; **B**, $\times 600$).

Fig. 24.7 *Chlamydia pneumoniae* detection from a direct sputum smear using a fluorescent-labeled monoclonal antibody, highlighting cytoplasmic inclusion ($\times 400$). (Courtesy DAKO Reagents, Carpinteria, CA.)

and the BD ProbeTec ET strand displacement amplification (BD Diagnostic Systems, Sparks, MD). Although commercial tests differ in their amplification methods and target nucleic acid sequences, the increased sensitivity of NAATs is ascribed to their ability to produce positive signals from as little as a single copy of the target DNA and do not require viable organisms. The assays target sequences on the plasmid, and all five have some degree of automation to facilitate testing and can provide results in the same day. Two NAATs have FDA approval for detecting *C. pneumoniae*; unfortunately, neither method has been thoroughly evaluated for diagnosing infections. Currently, no commercially available NAATs are approved for diagnosing *C. psittaci* infections.

Case check 24.2

In the Case in Point, the diagnosis of *C. trachomatis* infection was confirmed by a NAAT. These assays are generally rapid and highly sensitive and specific. Currently, five FDA-approved commercial NAATs are available; in-house tests can be used if they have been properly validated.

Antibody detection

Serologic assays have little value in the detection of *C. trachomatis* infections. Many individuals have chlamydial antibodies from previous infections, and because chlamydial infections tend to be chronic, it is difficult to demonstrate the traditional fourfold rise in *C. trachomatis* antibody titer between acute and convalescent stage specimens. Serologic testing of uncomplicated genital infections and screening of asymptomatic individuals is not recommended. Infections by the LGV strains are more invasive and therefore more likely to produce a detectable systemic antibody titer. Serologic testing in these patients can support a clinical diagnosis. Detection of high levels of IgM directed against *C. trachomatis* in neonates can be diagnostic of pneumonia.

Also because of high antibody levels in adults, serologic testing has limited value in diagnosing *C. pneumoniae* infections. However, human psittacosis diagnosis is often made by demonstrating a fourfold rise in antibody titer. A single antibody titer greater than 1:32 is suggestive of acute illness

in a symptomatic patient during an outbreak of psittacosis. The increase in the levels of antibodies is usually not demonstrable until the acute illness is over, however, and it is often weak or absent if appropriate antimicrobial therapy is given.

The microimmunofluorescence (MIF) assay has been the most widely used serologic test for the chlamydiae. Demonstration of high IgG titers can help the diagnosis of LGV, epididymitis, ectopic pregnancy, and human psittacosis. Commercial reagents for these assays are available. The MIF assay is considered the method of choice for detecting antibodies to *C. trachomatis*. EIA tests are also commercially available, but they have not been sufficiently evaluated to recommend their routine use.

Rickettsiaceae and similar organisms

The genera *Rickettsia* and *Orientia* are the only two genera in the family Rickettsiaceae. Most members of the rickettsial group are arthropod-borne, obligate intracellular pathogens that can grow only in the cytoplasm of host cells. These bacteria are extremely well adapted to their arthropod hosts. The primary hosts usually have minimal or no disease from their rickettsial infection. The arthropod host allows rickettsiae to persist in nature in two ways. First, rickettsiae are passed through new generations of arthropods by transovarial transmission. Because of this mechanism, arthropods are not only vectors for rickettsioses but also reservoirs. Second, arthropods directly inoculate new hosts with rickettsiae during feeding. An exception to this pattern occurs with *Rickettsia prowazekii*. In this case, the arthropod vector, the body louse, can die of the rickettsial infection, and humans act as a natural reservoir.

Rickettsia

Rickettsiae are short, nonmotile, gram-negative bacilli about 0.8 to $2.0\mu\text{m} \times 0.3$ to $0.5\mu\text{m}$ in size. The members of the genus *Rickettsia* have not been grown in cell-free media but have been grown in the yolk sacs of embryonated eggs and several cell lines. They lack enzymes for sugar metabolism and amino acid, nucleotide, and lipid synthesis. However, they can produce small amounts of ATP via the tricarboxylic acid pathway. Nutritional building blocks (e.g., amino acids) and ATP using an ATP/ADP translocase are acquired from host cells.

At least 30 species of *Rickettsia* are recognized, and most are divided into three groups according to the types of clinical infections they produce and phylogenetic clustering. The typhus group contains only two species: *R. prowazekii* and *R. typhi*. The spotted fever group includes several species generally recognized as human pathogens, such as *R. rickettsii*, *R. parkeri*, *R. philipii*, *R. conorii*, and *R. africae*. The transitional group contains *R. akari*, *R. australis*, and *R. felis*. Because the infective aerosol dose is low, *R. rickettsii*, *R. prowazekii*, *R. typhi*, and *R. conorii* are considered potential bioterrorism agents.

Following the bite of the arthropod vector, the rickettsiae are phagocytosed into endothelial cells (cells that line blood vessels), where they escape from the phagosome and replicate in the cytoplasm of the host cell. Replication in the nucleus also occurs. The rickettsiae pass directly through the plasma membranes of infected cells into adjacent cells without causing damage to the host cells. The rickettsiae are spread hematogenously throughout the host and induce vasculitis in internal organs, including the brain, heart, lungs, and kidneys.

Spotted fever group

Rocky Mountain spotted fever

The most severe of the rickettsial infections, Rocky Mountain spotted fever (RMSF) is caused by *R. rickettsii*. It was first described in the western United States during the latter part of the 19th century. It was not until the early 1900s that researchers demonstrated the infectious nature of the disease, when they infected laboratory animals with the blood of infected patients. The nature of the agent was a mystery because no bacteria were apparent on direct examination or on culture. However, researchers discounted a viral cause because the agent was nonfilterable. The organism was first seen using light microscopy in 1916. Since 2010, the CDC has used the category *spotted fever rickettsiosis* (SFR), which includes RMSF, *Rickettsia parkeri* rickettsiosis, Pacific Coast tick fever (*R. philipii*), and rickettsialpox (*R. akari*). The number of SFR cases in the United States has increased in the past two decades, and between 4500 and 6200 cases of RMSF have been reported annually since 2012.

RMSF is a zoonosis, and humans typically acquire the infection by tick bites. Ticks are the principal vectors and reservoirs for *R. rickettsii*. The most common tick vectors are *Dermacentor variabilis* (Fig. 24.8) in the southeastern United States and *Dermacentor andersoni* in the western part of the country. Other tick species, however, can be vectors. Ticks transmit the organism into humans via saliva, which is passed into the host when the tick feeds. After an incubation period of approximately 7 days, the patient experiences flulike symptoms for approximately 1 week. The symptoms include fever, headache, myalgia, nausea, vomiting, and rash. The rash, which may be hard to distinguish in individuals of color, begins as erythematous patches on the ankles and wrists during the first week of symptoms. The rash can extend to the palms of the hands and soles of the feet but normally does not affect the face. The maculopapular patches eventually consolidate into larger areas of ecchymoses.

Once disseminated, the organisms cause vasculitis in the blood vessels of the lungs, brain, and heart, leading to

pneumonitis, central nervous system (CNS) manifestations, and myocarditis. The patient experiences symptoms secondary to vasculitis, including decreased blood volume, hypotension, and disseminated intravascular coagulation. The mortality rate for untreated or incorrectly treated patients can be as high as 25%, although correct antimicrobial therapy with tetracycline or chloramphenicol lowers the rate to 3% to 6%.

Boutonneuse fever

Boutonneuse fever, also known as *Mediterranean spotted fever*, is caused by *R. conorii* and occurs in France, Spain, and Italy. *R. conorii* also causes Kenya tick typhus, South African tick fever, and Indian tick typhus. Like the agent for RMSF, this rickettsia is tickborne, and its reservoirs include ticks and dogs.

Boutonneuse fever clinically resembles RMSF. The rash involves the palms of the hands and soles of the feet, just as in RMSF. The rash of boutonneuse fever, however, also involves the face. In contrast with RMSF, this disease is characterized by the presence of taches noires (black spots) at the primary site of infection. Taches noires lesions are caused by the introduction of *R. conorii* into the skin of a nonimmune person. As the organism spreads to the blood vessels in the dermis, damage occurs to the endothelium. Edema secondary to increased vascular permeability reduces blood flow to the area and results in local necrosis.

Typhus group

The typhus group of rickettsiae includes the species *R. typhi* (which causes fleaborne typhus, also referred to as *endemic typhus* and *murine typhus*) and *R. prowazekii* (which causes louseborne or *epidemic typhus*). **Brill-Zinsser disease** is a recrudescent disease caused by reactivation of *R. prowazekii* years after epidemic typhus. Generally, the typhus rickettsiae differ from the other rickettsial groups in that they cause cell lysis, thereby releasing the rickettsiae. Other rickettsiae pass directly through an uninjured cell.

Fleaborne typhus

The arthropod vector for *R. typhi* is the oriental rat flea *Xenopsylla cheopis*, and the rat (*Rattus exulans*) is the primary reservoir. The cat flea, *Ctenocephalides felis*, can also harbor the organism. Because this flea infests many domestic and wild animals, it may be an important factor in the persistence of infection in humans. *Rickettsia felis*, described in 1990, also causes fleaborne typhus.

The rickettsiae survive in nature, to a lesser extent, by transovarial transmission. When a flea feeds on an infected host, the rickettsiae enter the flea's midgut, where they replicate in the epithelial cells. They are eventually released into the gut lumen. Humans become infected when fleas defecate on the surface of the skin while feeding. The human host reacts to the bite by scratching the site, allowing direct inoculation of the infected feces into abrasions. *R. typhi* can also be transmitted to humans directly from the flea bite itself.

In the 1940s, approximately 5000 cases of murine typhus were reported annually in the United States. Rigid control measures have reduced that number to fewer than 100 cases annually. The disease essentially occurs only in southern Texas and southern California. However, it continues to be a problem in warmer climates of the world in areas where rats and their fleas are present in urban settings. As is the case

Fig. 24.8 Dorsal view of *Dermacentor variabilis*, the American dog tick, a vector for Rocky Mountain spotted fever ($\times 20,000$). (Courtesy Janice Carr, Centers for Disease Control and Prevention, Atlanta, GA.)

with RMSF, the clinical course of endemic typhus includes fever, headache, and rash. Unlike RMSF, endemic typhus does not always produce a rash; only about 50% of those infected will have a rash. When the rash is present, however, it usually occurs on the trunk and extremities. Rash on the palms of the hands occurs rarely. Complications are rare, and recovery usually occurs without incident. Gastrointestinal symptoms, including anorexia, nausea, vomiting, and abdominal pain, are often present. The fatality rate is about 4% with treatment.

Louseborne typhus

The vectors for louseborne typhus include the human louse (*Pediculus humanus*; Fig. 24.9), squirrel flea (*Orchopeas howardii*), and squirrel louse (*Neohaematopinus sciurioperti*). The reservoirs are primarily humans and flying squirrels located in the eastern United States. The louse often dies because of rickettsemia, unlike vectors of other rickettsiae.

Louseborne typhus is still found commonly in areas of Africa and Central and South America where unsanitary conditions promote the presence of body lice. As seen during World War II, epidemic louseborne typhus can recur even in developed countries when sanitation is disrupted. More than 20,000 cases were documented during the 1980s, with the vast majority originating in Africa. Louseborne typhus resembles the other rickettsioses.

Lice are infected with *R. prowazekii* when feeding on infected humans. The organisms invade the cells lining the gut of the louse. They actively divide and eventually lyse the host cells, spilling the organisms into the gut lumen. When the louse feeds on another human, it defecates, and the infected feces are scratched into skin, just as in murine typhus. Following an incubation period of 1 to 3 days, the disease progression is like that of RMSF, including involvement of the palms of the hands and soles of the feet with the rash. Unlike the case with RMSF, the face may also be affected by rash. Patients have high fever, severe headache, and myalgia. The mortality rates for untreated patients can approach 40%, although mortality rates in treated patients are very low.

Brill-Zinsser disease, also called *recrudescence typhus*, is seen in patients who previously had louseborne typhus. *R. prowazekii* lies dormant in the lymph tissue of the human host until the infection is reactivated. Brill-Zinsser disease is a milder disease compared with louseborne typhus, and death is rare. Patients with latent infections constitute an important reservoir for the organism.

Fig. 24.9 The female head louse, *Pediculus humanus*, which is a vector for *Rickettsia prowazekii*, the agent of epidemic typhus (×40). (Courtesy Dr. Dennis D. Juranek, Centers for Disease Control and Prevention, Atlanta, GA.)

Transitional group

Rickettsialpox

Rickettsialpox is caused by *R. akari*, whose reservoir is the common house mouse, and the vector, the mouse mite *Liponyssoides sanguineus*. Rickettsialpox occurs in Korea and Ukraine and in the eastern United States, including the cities of New York, Boston, and Philadelphia. The infections occur in crowded urban areas where rodents and their mites exist.

Rickettsialpox has similarities to RMSF but is a milder infection and has a biphasic presentation. The rickettsial organism enters the human host following a mite (chigger) bite. The incubation period is about 7 days, after which the first phase presents as a papule at the site of inoculation. The papule progresses to a pustule and then to an indurated eschar. During this state, the bacteria spread hematogenously. This is followed by the second phase, when the patient becomes febrile. The patient also experiences headache, nausea, chills, and a papulovesicular rash. Unlike RMSF, the rash of rickettsialpox appears on the face, trunk, and extremities and does not involve the palms of the hands or soles of the feet. Rickettsialpox symptoms resolve without medical attention in 2 to 3 weeks.

Orientia

Scrub typhus is a disease that occurs in India, Pakistan, Myanmar, eastern Russia, Asia, and Australia. The causative agent is *Orientia* (formerly *Rickettsia*) *tsutsugamushi*. The vector is the *Leptotrombidium deliense* mite, and the reservoir is the rat. Because mites only feed once during their life, they are not considered important reservoirs for human disease. Mites are also reservoirs because the bacteria are transmitted transovarially. The transmission of *O. tsutsugamushi* to the human host is followed by an incubation period of approximately 2 weeks. A tache noire, like that of boutonneuse fever, often forms at the site of inoculation. The normal rickettsial symptoms of fever, severe headache, and rash are also present. The macular to papular rash starts on the trunk and spreads to the extremities but is present on less than 50% of the patients. Unlike the case with RMSF, the rash does not involve the palms of the hands and soles of the feet, and the face is also not involved. Systemic lymphadenopathy, heart failure, and CNS involvement can be present. Without treatment, mortality approaches 30%.

Laboratory diagnosis of rickettsial diseases

Because of their infectious nature, isolation of the rickettsiae is not recommended and should be attempted only by biosafety level 3 laboratories. If culture is attempted, blood should be collected as early in the disease course as possible. Methods for immunohistochemical testing of tissue specimens have been established for several rickettsial diseases. Monoclonal antibodies directed against the spotted fever or typhus group have been used, but no antibody is commercially available. NAATs are particularly useful for eschar specimens. Only NAATs and immunohistochemical assays can provide a diagnosis in the acute stage, when treatment is critical. Unfortunately, neither method is readily available.

Typically, serologic assays are the only laboratory tests performed for the diagnosis of rickettsial diseases. Unfortunately, these methods can confirm a diagnosis only

in convalescent specimens and offer little help in diagnosing acute infections that could guide antimicrobial therapy. An acute blood sample should be taken as early as possible, and a second sample should be taken 1 to 2 weeks later. If the second sample does not detect a fourfold or greater increase in titer, a third sample is recommended 4 weeks after onset of symptoms.

The immunofluorescent antibody (IFA) test is considered the gold standard method for antibody detection. Because of cross-reactivity among members of the same groups (spotted fever and typhus), generally only group-specific antibody testing is available. Antibodies to certain rickettsial species are known to cross-react with bacteria in the genus *Proteus*. This gave rise to the Weil-Felix agglutination test. Because this assay does not use rickettsial antigens, it is nonspecific and rarely used in the United States. However, because of its low cost, it is used in some other countries. An agglutination test using latex beads coated with rickettsial antigens is commercially available for the diagnosis of RMSF (Panbio, Baltimore, MD) as are EIAs.

Anaplasmataceae

The family Anaplasmataceae contains several genera of importance to human and veterinary medicine. *Anaplasma* and *Ehrlichia* are the most significant for human disease. Members of the family are small, nonmotile, obligate intracellular bacteria. They replicate within membrane-derived vacuoles within the cytoplasm. Most members of the family grow in vertebrate hosts and one invertebrate vector. In vertebrate hosts, they reside in cells of hematopoietic origin.

Ehrlichia

Ehrlichiosis was first noted in France in the 1930s in dogs. Postmortem examination revealed rickettsial-like inclusions in the monocytes of the dead animals. These rickettsiae were named *Rickettsia canis*. They were obligately intracellular, arthropod-borne coccobacilli. They differ from members of the rickettsiae in that they multiply in the phagosomes of host leukocytes and in other cells derived from the bone marrow, not in the cytoplasm of endothelial cells.

Because these organisms grew within host cell vacuoles, they were reclassified into a new genus, *Ehrlichia*, in 1945. The ehrlichiae have a developmental cycle like that of the chlamydiae. There are two forms: the denser, infective EB, and the RB that replicates in the phagosome and prevents phagolysosome formation. As the cells divide within the phagosome, they develop into **morulae** (Latin for “mulberry”; Fig. 24.10). Morulae are round to oval clusters of bacteria 1 to 3 μm in diameter that stain blue in Wright’s and Giemsa stains. As the host cell ruptures, the morulae break into many individual EBs, which continue the infective cycle.

Ehrlichia chaffeensis causes *E. chaffeensis* ehrlichiosis, formerly called **human monocytic ehrlichiosis** because the bacteria primarily reside in mononuclear cells such as monocytes. Most cases occur in the United States, but some cases are reported in Europe, Africa, and South and Central America. In the United States, about 1600 cases are reported annually, and most cases are found in the southeastern and south-central states as well as in the Mid-Atlantic states. In 2019, four states, Missouri, Arkansas, New York, and North Carolina, accounted for over one half of all reported cases of

Fig. 24.10 *Anaplasma* morula (arrow) in an infected white blood cell ($\times 1000$).

ehrlichiosis. Most cases occur in the summer months June and July, which is expected for a tickborne disease. *E. chaffeensis* causes the most cases, but *Ehrlichia ewingii*, the second most common, produces a disease indistinguishable from *E. chaffeensis*. Currently, no serologic test can distinguish these agents.

The seroprevalence of *E. chaffeensis* ranges from 1.3% to 12.5% in Arkansas and Tennessee, two states with a high incidence of infection. This indicates that cases may be underreported. Natural hosts of the organism include dogs, deer, and humans, with the lone star tick (*Amblyomma americanum*) being the primary vector. This tick also transmits *E. ewingii*. *E. muris eauclairensis* is the third most common cause of ehrlichiosis in the United States, with most cases occurring in Minnesota and Wisconsin, and is transmitted by the black-legged tick (*Ixodes scapularis*).

Many patients with *E. chaffeensis* ehrlichiosis experience asymptomatic infection. The organism has an incubation period of 5 to 10 days. Patients often experience fever, headache, malaise, myalgia, and nausea. Vomiting, diarrhea, cough, and joint pain are occasionally present. A petechial, macular, or maculopapular rash is sometimes present (57%) in pediatric patients infected with *E. chaffeensis*; however, adults rarely experience a rash (<30%). Patients may also have evidence of leukopenia and neutropenia, thrombocytopenia, and elevated liver enzyme levels. Patients can experience severe complications, including a toxic shock-like syndrome presentation, CNS involvement, and acute respiratory distress syndrome. Mortality rates are approximately 2% to 3%.

Direct staining (Giemsa or Wright) of peripheral blood smears or buffy coats for morulae can be used for diagnosing *E. chaffeensis* infections; however, this method is not very sensitive (29%). The bacteria are primarily found in monocytes, and the percentage of cells infected is less than 10%. Antigen detection in tissues, such as bone marrow, liver, and spleen, has been described. Again, the sensitivity is low (40%), and cross-reaction with other species has been noted. This leaves NAATs as a frequently used method for direct detection of *E. chaffeensis* from whole blood. The use of real-time PCR and multiplex PCR has been described. The bacteria can be isolated from peripheral blood in cell culture, but this method is rarely used. Most cases of *E. chaffeensis* ehrlichiosis are diagnosed retrospectively by serologic testing demonstrating a fourfold increase in IgG antibody. The IFA test is the most widely used method. Significant antibody cross-reactivity has been seen among *Ehrlichia* spp. and between *Ehrlichia* and *Anaplasma*.

Anaplasma

Anaplasma phagocytophilum, formerly known as *Ehrlichia phagocytophilum*, causes the disease **human granulocytic anaplasmosis (HGA)**. The incubation period for HGA is 1 to 5 days. The symptoms closely resemble those of *E. chaffeensis* ehrlichiosis and include fever, headache, malaise, and myalgia. Less than 10% of infected individuals have a rash.

The number of HGA cases is probably underreported. Annually, about 4000 cases are reported in the United States, with most cases occurring in the upper Northeast region. In 2018, the highest rates per 100,000 people were in Vermont (391), Maine (355), New Hampshire (158), and Rhode Island (141). Significant infection rates also occur in Minnesota (88) and Wisconsin (63). Natural hosts include deer, rodents, horses, cattle, and humans. Tick vectors include *I. scapularis* in the northeast and *Ixodes pacificus* along the west coast. The geographic range of anaplasmosis is increasing corresponding to the blacklegged tick's expanding range.

Typical laboratory test results include elevated transaminase levels, thrombocytopenia, and leukopenia with lymphopenia. As with *E. chaffeensis* ehrlichiosis, staining of peripheral blood buffy coats can be used to diagnose HGA. The morulae are found in granulocytes (see Fig. 24.10), and the sensitivity is about 60%. The percentage of granulocytes infected can reach 40%. Diagnosis can also be made by using direct antigen detection, NAATs, and isolation in cell cultures. IFA serologic kits are available for the detection of antibodies to *A. phagocytophilum*.

Coxiella

Coxiella burnetii is the only species in the genus. This organism differs in several ways from many members of the families Rickettsiaceae and Anaplasmataceae. For example, *C. burnetii* has been grown in cell-free media and should be considered a facultative intracellular parasite. The bacterium does not transport ATP across its plasma membrane, and it develops within the phagolysosomes of infected cells. The acidic environment activates its metabolic enzymes. The bacteria exist in two forms. The large-cell variant is rod shaped (0.4–1.5 µm) and metabolically active inside host cells. Under adverse conditions, the large-cell variant converts into the denser small-cell variant (0.22 µm) that survives harsh environmental conditions. Another distinguishing feature is that *C. burnetii* is generally not transmitted by arthropods, although it is known to infect more than 12 genera of ticks and other arthropods. The bacteria can infect fishes, birds, rodents, livestock, and other mammals.

C. burnetii is the causative agent of Q (query) fever, a disease found worldwide. Roughly 160 cases are reported annually in the United States. Q fever is highly contagious and, as such, is considered a potential bioterrorism agent (see Chapter 30). Most infections are spread by the inhalation of dried birthing fluids of several animals. Therefore occupational hazards include ranching or livestock management. The ingestion of unpasteurized milk is also a recognized risk factor. Approximately 50% of infected individuals will remain asymptomatic. In the remaining cases after an incubation period of 2 to 3 weeks, acute Q fever generally has an abrupt onset of an undifferentiated febrile disease consisting

of high fever that can be accompanied by chills, headaches, myalgia, arthralgia, cough, and rarely, a rash. Patients may present with elevated liver enzyme levels, increased erythrocytic sedimentation rate, and thrombocytopenia. Because of the rapid dissemination of the bacteria, several tissues can be infected. Chronic disease occurs in a small number of patients and can result in vascular disease, endocarditis, and bone and joint infections.

Because the symptoms vary among patients and can be difficult to distinguish from other diseases, it can be a challenging disease to diagnose. The laboratory diagnosis of Q fever can be made by direct IFA of infected tissue. However, except for heart tissue in cases of endocarditis, infected tissue contains low numbers of bacteria. NAATs, such as the PCR assay, have also been successful in diagnosing acute and chronic infections; whole blood and buffy coats are often successful in detecting the organism. However, NAAT sensitivity drops significantly after antibody production, which occurs about 2 weeks after infection. *C. burnetii* is highly contagious; isolation in cell cultures should be attempted only in biosafety level 3 facilities. Several serologic assays have been described for detecting antibodies in acute and chronic cases. The IFA test is the method of choice. EIA kits are commercially available and FDA approved and have sensitivities and specificities comparable with those of the IFA test.

POINTS TO REMEMBER

- Chlamydiae and rickettsiae are obligate intracellular organisms.
- *Chlamydia trachomatis* is the most common sexually transmitted bacterial pathogen, and certain serovars are associated with trachoma, which can result in blindness.
- The LGV strains of *C. trachomatis* are more invasive, producing a more serious infection and pronounced antibody response.
- NAATs are better assays for the diagnosis of *C. trachomatis* infections compared with cultures.
- *C. pneumoniae* is a relatively common respiratory tract pathogen considered responsible for many cases of community-acquired pneumonia.
- *C. psittaci* is the cause of psittacosis, also known as *parrot fever* or *ornithosis*. This bacterium produces lower respiratory tract infections in humans.
- The *Rickettsia* spp. are important human pathogens responsible for several diseases, including RMSF, rickettsialpox, and typhus.
- The *Rickettsia*, *Orientia*, *Ehrlichia*, and *Anaplasma* are typically transmitted to humans by arthropod bites.
- *Ehrlichia* and *Anaplasma* are intracellular parasites of white blood cells—mononuclear cells and granulocytes, respectively.
- *Coxiella burnetii* is the causative agent of Q fever. Infection is most often transmitted by inhalation of dried birthing fluids. The ingestion of unpasteurized milk is also a risk factor.
- *C. burnetii* differs from the rickettsiae by developing within the phagolysosome of infected cells and is generally not transmitted by arthropods. *C. burnetii*, unlike the *Rickettsia* spp., has been grown in cell-free media.

LEARNING ASSESSMENT QUESTIONS

- Which organisms should be considered as probable causes of neonatal conjunctivitis?
 - Chlamydia trachomatis* and *Chlamydia pneumoniae*
 - Chlamydia pneumoniae* and *Chlamydia psittaci*
 - Chlamydia trachomatis* and *Neisseria gonorrhoeae*
 - Chlamydia pneumoniae* and *Neisseria gonorrhoeae*
- Which *Chlamydia trachomatis* serotypes are associated with lymphogranuloma venereum?
 - A, B, and C
 - A to K
 - D to K
 - L1, L2, and L3
- How does psittacosis or ornithosis present in human infections?
 - Endocarditis
 - Pneumonia
 - Nausea and vomiting
 - Tissue abscess
- What is the most common laboratory method used to diagnose rickettsial diseases?
 - Serology
 - Growth in cell monolayers
 - Direct immunofluorescent assay
 - Histologic tissue stain with Giemsa stain
- Which cells do the *Ehrlichia* typically infect in humans?
 - Hematopoietic stem cells
 - Reticulocytes
 - Granulocytes
 - Monocytes
- During human infection by the rickettsiae, where do the bacteria usually replicate?
 - Attached to the outside of the plasma membrane
 - Within the endosome
 - Free in cytoplasm
 - Within a phagolysosome
- Which stain should be performed on a conjunctival scraping for microscopic examination for the diagnosis of inclusion conjunctivitis?
 - Gram
 - Giemsa
 - Machibavello
 - Fluorescent antibody
- Which time of year do most cases of Rocky Mountain spotted fever occur in the United States?
 - Winter
 - Spring
 - Summer
 - Fall
- Areas of overcrowding and poor personal hygiene are known for a high incidence of infections by which organism?
 - Rickettsia prowazekii*
 - Rickettsia coronii*
 - Rickettsia akari*
 - Rickettsia typhi*
- In July, a 28-year-old male patient presents to his primary care provider complaining of headache, malaise, and myalgia. He is also found to have a fever, but no rash is present. His medical history is unremarkable, and he reports that he recently returned from a camping trip in Maine. A complete blood count revealed leukopenia, and clumps of

blue inclusions about 2 μ m in diameter were found in the neutrophils. What is the most likely diagnosis?

- Ehrlichia chaffeensis* ehrlichiosis
 - Human granulocytic anaplasmosis
 - Flea-borne typhus
 - Q fever
- For the neonate described in the Case in Point, what other clinical conditions could have resulted from infection with the causative organisms?
 - How does lymphogranuloma venereum differ from other sexually transmitted diseases caused by *Chlamydia trachomatis*?
 - Which types of infections are associated with *Chlamydia pneumoniae*?
 - How does *Coxiella burnetii* differ from the *Rickettsia* spp.?

9. Justify the use of serologic assays for diagnosing *M. pneumoniae* infections.
10. Describe two selective media for the detection of the mycoplasmas.
11. Evaluate the use of different classes of antimicrobial agents to treat mycoplasmal infections.
12. Provide recommendations for the proper interpretation and reporting for *Mycoplasma* and *Ureaplasma*.

KEY TERMS

Cell wall deficient

L-forms

Pleuropneumonia-like organism (PPLO)

Nongonococcal urethritis (NGU)

Pelvic inflammatory disease (PID)

Primary atypical pneumonia

T-strain mycoplasma

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics of the *Mycoplasma* and *Ureaplasma*, and how they differ from other bacterial species.
2. Name the clinical specimens from which the mycoplasma species are most likely to be isolated.
3. Compare the clinical diseases caused by *Mycoplasma pneumoniae*, *Mycoplasma hominis*, *Mycoplasma genitalium*, *Mycoplasma fermentans*, and *Ureaplasma urealyticum*.
4. Evaluate the recovery of *M. hominis* from a genital specimen.
5. Compare the pneumonia caused by *Mycoplasma pneumoniae* with that caused by *Streptococcus pneumoniae*.
6. Discuss the possible roles of *M. hominis* and *U. urealyticum* in infections of low-birth-weight and high-risk neonates.
7. Discuss the clinical manifestations of *Mycoplasma* spp. in immunocompromised patients.
8. Analyze the diagnostic methods appropriate for the detection and identification of mycoplasmal and ureaplasma infections including specimen collection, transport, storage, and appropriate media.

Case in point

A premature male neonate in the neonatal intensive care unit, who weighed 1.5 lb at birth (low birth weight), developed signs of meningitis, and a lumbar puncture was performed. The results of a white blood cell count of cerebrospinal fluid (CSF) were negative. The Gram-stained smear showed "no organisms seen," and the result of routine culture at 3 days was reported as "no growth." The infant was still symptomatic at this time, and the pediatric infectious disease physician, after consultation with the clinical microbiologist, performed another lumbar puncture and ordered additional cultures. An organism was recovered by the laboratory.

Issues to consider

After reading the patient's case history, consider:

- The cause of meningeal infections in the given patient population
- Supporting laboratory findings and how they help establish the diagnosis
- Methods for recovery of the suspected causative agent

This chapter discusses bacteria within the class Mollicutes, the smallest self-replicating organisms once thought to be viruses because their small size allowed them to pass through filters, hence the name *filterable*. Members of this class are also referred to by the common names *mollicute* or *mycoplasma*. This group of bacteria is characterized by permanently lacking a cell wall. They range in size for coccoid forms from approximately 0.2 to 0.3 μm in diameter to tapered rods of approximately 1 to 2 μm in length and 0.2 to 0.3 μm in diameter. Seven families, at least 12 genera, and over 200 species of mollicutes have been described. At least 16 species of mollicutes have been isolated from humans.

Mycoplasma and *Ureaplasma* are two of the four genera in the family Mycoplasmataceae. Numerous species of *Mycoplasma* and *Ureaplasma* have been identified in plants and animals; however, the following species are the most significant human pathogens (Table 25.1):

- *Mycoplasma pneumoniae*, which causes respiratory disease
- *Mycoplasma hominis*, associated with urogenital tract disease
- *Ureaplasma urealyticum*, associated with urogenital tract disease

The family Acholeplasmataceae contains five genera, including *Acholeplasma*. Members of this genus do not appear to cause significant infections in humans.

General characteristics

The first *Mycoplasma* sp. was isolated in the late 1800s from a cow with pleuropneumonia. Later, a mycoplasma was isolated from humans and was referred to as a **pleuropneumonia-like organism (PPLO)** and the *Eaton agent*, after the researcher who first isolated it from humans. This human isolate was ultimately named *Mycoplasma pneumoniae*. Because of the absence of a cell wall, the mycoplasmas are pleomorphic and are not visible microscopically with the Gram stain. In addition, this characteristic makes them resistant to cell wall-active antibiotics, such as the penicillins and cephalosporins. They were originally grouped under the general term **cell wall-deficient** bacteria given the absence of a cell wall. They are not, however, classified as **L-forms**, which are bacteria that have temporarily lost their cell wall attributable to environmental conditions. Table 25.2 compares features of the three genera found in human specimens.

Mycoplasmas are generally slow-growing, highly fastidious, facultative anaerobes requiring complex media containing nucleic acid precursors, cholesterol, and fatty acids for growth; important exceptions include aerobic *M. pneumoniae* and the more rapidly growing *M. hominis*. The *Acholeplasma* do not require cholesterol supplements in laboratory media. The mycoplasmas produce small colonies ranging in size from about 15 μm to over 300 μm in diameter. *Mycoplasma* spp. often grow embedded beneath the surface of solid media; therefore transferring colonies with a loop is ineffective. On solid media, some species (e.g., *M. hominis*) form colonies with slightly raised centers, giving the classic “fried egg” appearance (Fig. 25.1). In the laboratory, mycoplasmas are common and hard to detect contaminants of cell cultures.

Table 25.2 Human clinical isolates in the class Mollicutes

Feature	<i>Mycoplasma</i>	<i>Ureaplasma</i>	<i>Acholeplasma</i>
Cell wall deficient	+	+	+
Gram stain	–	–	–
Penicillin susceptible	–	–	–
Urease activity	–	+	–
Lack of cell wall induced in hypertonic solution and by penicillin, lysozyme, or salts	–	–	–
Exists in nature as a free-living organism	–	–	+
Pleomorphic shape	+	+	–
Other shared characteristics	Smaller than other bacteria; close in size to myxoviruses		
	Smaller genome than other bacteria		
	Lower guanidine-to-cytosine ratio than most bacteria		
	Limited metabolic activity (i.e., fastidious)		
	Many mollicutes contain DNase		
+, Feature present; –, feature absent.			

Table 25.1 Divergent ecosystems inhabited by genera of the class Mollicutes

Ecosystem	<i>Mycoplasma</i>	<i>Ureaplasma</i>	<i>Acholeplasma</i>	<i>Spiroplasma</i>	<i>Anaeroplasm</i>
Soil and grasses	–	–	–	–	–
Crops and plants	–	–	–	+	–
Mown hay	–	–	–	–	–
Water	–	–	+	–	–
Deciduous trees	–	–	–	+	–
Humans	+	+	–	–	+
Cattle	+	+	–	–	+
+, Present in ecosystem; –, rarely associated with ecosystem.					

The mycoplasmas adhere to the epithelium of mucosal surfaces in the respiratory and urogenital tracts and are not eliminated by mucous secretions or urine flow. Fig. 25.2 depicts electron micrographs of ciliated tracheal epithelial cells before and after *M. pneumoniae* adherence. *M. pneumoniae* utilizes the P1 adhesion and other proteins to adhere to host cells of the respiratory tract. P1 is associated with a polar extension called an attachment organelle or foot. The organelle is responsible for cytoadherence. This ability of *M. pneumoniae* to adhere and attach to hosts' cells is crucial for the bacteria to survive and infect. Once attached, the host's mucociliary clearance mechanisms are compromised and prevented from eliminating the organism, damaging the respiratory epithelial cells. Fig. 25.3 is an electron micrograph demonstrating the shape of *M. pneumoniae* and its orientation of attachment. Although *M. pneumoniae* mainly inhabits the surface of the respiratory epithelial cells, it may also invade tissues and replicate intracellularly.

Mycoplasma spp. indigenous to humans are listed in Table 25.3. The human mollicutes are susceptible to adverse environmental conditions, such as heat and drying. Transmission of mollicutes in humans can occur via direct sexual contact,

from mother to child during delivery or in utero, and by respiratory secretions or fomites in cases of *M. pneumoniae* infections.

Clinical infections

Mycoplasma pneumoniae

M. pneumoniae does not occur as a normal commensal organism; therefore its isolation is always significant and pathognomonic. Infection can result in a relatively common pneumonia known as **primary atypical pneumonia** or *walking pneumonia*. The clinical manifestations resemble those caused by *Chlamydia pneumoniae*. The disease differs from the typical pneumonia caused by *Streptococcus pneumoniae* in that it is milder and has a higher incidence in young adults. Although infection is not considered seasonal, more cases occur in autumn and early winter. Outbreaks also have been noted when adolescents return to school in the fall.

Fig. 25.1 Typical large *Mycoplasma* colony showing "fried egg" appearance. (Courtesy Bionique Testing Laboratories, Saranac Lake, NY)

Fig. 25.3 Electron micrograph of *Mycoplasma pneumoniae* attaching by specific attachment features to ciliated trachea ($\times 100,000$). Arrow indicates attachment organelle. c, Cilia; m, mycoplasma; mv, microvilli.

Fig. 25.2 Electron micrographs showing the effect of *Mycoplasma pneumoniae* on ciliated tracheal cells. **A**, Infected animal model. **B**, Uninfected animal model ($\times 20,000$).

Table 25.3 *Mycoplasma* species indigenous to humans

Mycoplasma species	Usual habitat	Reported frequency	Colony morphology ^a
<i>M. salivarium</i>	Oropharynx	Very common	Large, "fried egg"
<i>M. orale</i>	Oropharynx	Common	Small, spherical
<i>M. buccale</i>	Oropharynx	Uncommon	Large, fried egg
<i>M. faucium</i>	Oropharynx	Uncommon	Large, fried egg
<i>M. lipophilum</i>	Oropharynx	Rare	Large, fried egg
<i>M. pneumoniae</i>	Oropharynx	Common (with disease)	Small, spherical, granular
<i>M. fermentans</i>	Oropharynx	Rare	Small, fried egg, spherical
<i>M. hominis</i>	Urogenital tract	Uncommon	Large, fried egg, vesiculated peripheral zone
	Oropharynx	Uncommon	
<i>M. genitalium</i>	Urogenital tract	Common (9%–50% of women)	Tiny, spherical, fried egg, granular
	Urogenital tract	Occasional	
<i>Ureaplasma urealyticum</i>	Urogenital tract	Very common (81% of women; 30%–50% of men)	Tiny, spherical, fried egg, granular
<i>Acholeplasma laidlawii</i>	Oropharynx	Rare	Small, fried egg, spherical

^aRelative sizes: large, greater than 100 nm; small, 50 to 100 nm; tiny, less than 50 nm.

M. pneumoniae is extremely susceptible to desiccation because it lacks a cell wall; hence, transmission is probably through aerosol droplet spray produced while coughing.

M. pneumoniae causes 4% to 8% of reported pneumonias in the general population and up to 70% in confined populations, such as those in military settings, prisoners, and college students. School-age children and young adults are especially susceptible to infection. Epidemics are known to occur in these populations. Historically, clinical disease was uncommon in very young children and older adults. However, recent outbreaks and endemicity have been reported in older adults and children younger than 5 years of age. A recent study found that 40% of 830 Chinese children with community-acquired pneumonia tested positive for *M. pneumoniae* by polymerase chain reaction (PCR).

Many infections are asymptomatic or very mild. The most common presentation is tracheobronchitis often accompanied by pharyngitis. About one third of infected patients demonstrate clinically apparent pneumonia (Fig. 25.4). The incubation period is usually 2 to 3 weeks, and early symptoms are nonspecific, consisting of headache, low-grade fever, malaise, and anorexia. Dry cough and earache are accompanying symptoms. Extrapulmonary complications, including cardiovascular, central nervous system, dermatologic, and gastrointestinal problems, are rare occurrences. In addition, *Mycoplasma pneumoniae* infection has been associated with chronic lung disease and bronchial asthma. *M. pneumoniae* is not associated with infections of the urogenital tract. It has, however, been implicated as a co-infection or cofactor in epidemic group A meningococcal meningitis (*Neisseria meningitidis*) and infant pneumonitis. Recently, a unique virulence factor known as community acquired respiratory distress syndrome (CARDS) toxin has been identified and associated in the pathogenesis of *M. pneumoniae* infections. It appears that the CARDS toxin helps in the colonization and development of disease, causing an inflammatory response and subsequent airway dysfunction.

Fig. 25.4 Typical chest x-ray of a patient with a 3-week course of atypical pneumonia. Note nonspecific interstitial pneumonia and a patchy infiltrate delineated by a feathery outline.

Genitourinary tract infections associated with the mollicutes

Although the mollicutes do not cause vaginitis, *M. hominis*, *M. genitalium*, and *U. urealyticum* are associated with infections of the urogenital tract. *M. genitalium* and *U. urealyticum* probably play a role in **nongonococcal urethritis (NGU)**. *M. hominis* and *U. urealyticum* are frequently isolated from asymptomatic sexually active individuals, making interpretation of a positive culture difficult. *U. urealyticum* has been recovered from more than 60% of healthy sexually active females. Because these species are opportunistic pathogens, the immune status of the host is an important factor in the

occurrence and severity of disease. In addition, it has been reported that among sexually active individuals, the rate of colonization is directly related to the number of sexual partners. Higher rates of colonization have been noted in adults of lower socioeconomic status.

M. hominis is found in the lower genitourinary tracts of approximately 50% of healthy adults but has not been reported as a cause of NGU. The organism may, however, invade the upper genitourinary tract and cause salpingitis, pyelonephritis, pelvic inflammatory disease (PID), or postpartum fever. It might also play a role in bacterial vaginosis. *Ureaplasma parvum* (*U. urealyticum* biovar 1) and *U. urealyticum* (*U. urealyticum* biovar 2) do not cause disease in the female lower genital tract. However, *U. urealyticum* has been associated with NGU in men, whereas *U. parvum* has not, although recent studies have found that both serovars often occur together, and horizontal gene transfer between the two species is common. Therefore maintaining separate serovars might not be valid. Evidence also does not support the role of the *Ureaplasma* spp. causing upper female genitourinary tract disorders.

While somewhat controversial, the urogenital mollicutes have also been linked to female infertility. Most females with infertility suffer from inflammation of the oviduct and nearby tissue. *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are the most common causes of this condition, although other infectious agents have been implicated. The mollicutes can be part of the normal microbiota of the vagina and cervix. However, they can ascend and colonize the endometrium, fallopian tubes, and ovaries and cause inflammation and damage to the ciliated epithelium of the human fallopian tube. This can lead to scarring and infertility.

Ureaplasma spp. and *M. hominis* can be transmitted to neonates during delivery and have been associated with chorioamnionitis, congenital bacteremia, and pneumonia, as well as development of chronic lung disease in premature infants. Although it is not a primary cause of chronic lung disease, *U. urealyticum* is a common organism isolated from tracheal aspirates of low-birth-weight infants with respiratory disease; 14% of infections were in newborns delivered by cesarean section, thus indicating that infection occurred in utero and not during passage through the birth canal. *M. hominis* and *Ureaplasma* spp. have been recovered from the CSF of certain high-risk newborns, including preterm and low-birth-weight infants. Table 25.4 summarizes the known association of genital mollicutes with urogenital and newborn diseases. It has been recommended that culture for these organisms be attempted when the CSF specimen from a newborn with evidence of meningitis is negative for bacteria on Gram stain and routine bacteriology culture. However, because healthy neonates can be asymptotically colonized with mollicutes, routine screening cannot be justified.

Mycoplasma genitalium, first isolated in 1980, has been associated with NGU, cervicitis, endometriosis, and PID. There is also evidence linking *M. genitalium* to some cases of tubal sterility. Its prevalence is unknown, but PCR assays found *M. genitalium* more frequently in urethral samples taken from men with acute NGU than in those from men without urethritis. It is estimated that *M. genitalium* could be responsible for 30% of persistent urethritis in males.

Case check 25.1

In the Case in Point, CSF was culture negative for the more common causes of neonatal meningitis: group B *Streptococcus*, *Escherichia coli*, and *Listeria monocytogenes*. Both *M. hominis* and *U. urealyticum* have been isolated from the CSF of low-birth-weight infants. Because of the absence of a cell wall, these bacteria are not visible with Gram stain, so the lack of bacteria seen in direct Gram-stained smear supports the diagnosis.

In immunocompromised individuals, bacteremia and invasive disease of the joints and respiratory tract caused by mollicutes species have occurred. *U. urealyticum* has been reported to cause chronic inflammatory diseases, such as arthritis and cystitis, in patients with hypogammaglobulinemia. *Mycoplasma* isolates have been intermittently associated with patients with endocarditis, sternal wound infections, and arthritis.

Mycoplasma fermentans

Mycoplasma fermentans has been noted as a likely opportunistic respiratory pathogen. It is not known how often *M. fermentans* occurs in the respiratory tracts of healthy children, but it has been detected in throats of patients with lower respiratory tract infection, in some of whom a specific causative agent was not identified. Other groups of patients from whom *M. fermentans* has been recovered include adult patients with respiratory illness and those with acquired immunodeficiency syndrome (AIDS). *M. fermentans* has been isolated from tissue in patients with and without AIDS who died of systemic infection. *M. fermentans* has also been isolated from synovial fluid of patients with rheumatoid arthritis.

Laboratory diagnosis

Because they lack a cell wall, the mollicutes will not be visible by Gram stain. A DNA fluorescent stain (e.g., acridine orange) can be used, but this is not specific for the mollicutes. Laboratory diagnosis is often based on a nucleic acid amplification test (NAAT), culture, and serology. Immunochromatographic tests were released commercially in the 1980s. However, the assays demonstrated low sensitivity and specificity and are not recommended.

Specimens for culture and nonculture detection of the mollicutes include blood, synovial fluid, amniotic fluid, urine, prostatic secretions, semen, bronchoalveolar lavage fluid, as well as swabs from the nasopharynx, throat, cervix, and urethra. If swabs are used, it is important to vigorously rub the tissue because the mollicutes are strongly cell associated. Tissue samples may also be submitted for culture.

Specimen collection and transport

The absence of a cell wall makes all mollicutes extremely sensitive to drying and heat. Ideally, specimens should be inoculated at the bedside. If this is not possible, specimens should be delivered immediately to the laboratory in a transport

Table 25.4 Summary of association of genital mollicutes with urogenital and newborn diseases

Disease, target population	<i>Mycoplasma hominis</i>	<i>Mycoplasma genitalium</i>	<i>Ureaplasma</i> spp.	Comments
Nongonococcal urethritis	None	Weak	Strong ^a	<i>Ureaplasma</i> spp. cause some cases, but the proportion is unknown.
Prostatitis	None	Weak	None	An association with a few cases of chronic disease has been reported; a causal relation is unproven.
Epididymitis	None	None	Weak	<i>Mycoplasma</i> spp. are not an important cause.
Vaginitis and cervicitis	None	None	None	<i>M. hominis</i> is often associated with disease, but a causal relation is unproven.
Pelvic inflammatory disease	Strong	Strong	None	<i>M. hominis</i> causes some cases, but the proportion is unknown.
Postpartum fever	Strong	None	Weak	Recent studies indicate that <i>M. hominis</i> may be a major cause.
Urinary calculi	None	None	Weak	<i>Ureaplasma</i> spp. cause calculi in male rats, but no convincing evidence exists that they cause natural human disease.
Pyelonephritis	Strong	None	None	<i>M. hominis</i> causes some cases.
Involuntary infertility	Weak	Weak	Weak	<i>Ureaplasma</i> spp. are associated with altered motility of sperm.
Chorioamnionitis	Strong	None	Strong	An association exists, but a causal relation is unproven.
Low birth weight	None	None	Strong	An association exists, but a causal relation is unproven.
Neonatal infections, including sepsis, pneumonia, meningitis	Strong	None	Strong	Further clarification is needed, but importance is growing in a selected prenatal population.
Neonatal period, particularly preterm delivery, very low birth weight; clinical signs compatible with meningitis (CSF), pneumonia (trachea), sepsis (blood)	Strong	Weak	Strong	These findings need further clarification because most neonatal infections resolve without therapy, but in low socioeconomic groups, the diagnostic workup of newborns should include CSF and blood cultures for detection of mycoplasmas. This includes low-birth-weight and preterm newborns, in whom traditional CSF cell counts and cultures would be negative.

CSF, Cerebrospinal fluid.

^a*U. urealyticum* has been implicated in nongonococcal urethritis, while *U. parvum* has not been implicated.

medium, such as SP4 (sucrose phosphate buffer, *Mycoplasma* base, horse serum [20%], and neutral red) or Shepard 10B broth or 2SP, which are designed for *Mycoplasma*. Cotton-tipped swabs and wooden shafts should be avoided because of possible inhibitory effects. Swabs should be made of Dacron polyester or calcium alginate with aluminum or plastic shafts, and the swabs should be removed when the sample is placed in a transport medium. On arrival in the laboratory, the specimens should be frozen at -70°C if plating within 24 hours is not possible.

Nucleic acid amplification tests

Real-time PCR assays are the preferred method for the detection of many mollicutes. NAATs have the advantage of detecting bacteria earlier in the course of infection than serology, are more sensitive than serology, and have a rapid turnaround time. PCR assays can also differentiate *Ureaplasma* spp. A drawback to NAATs is that they cannot distinguish between

asymptomatic carriage and acute infection. Patients with *M. pneumoniae* infections can persistently harbor the organism for various lengths of time after the acute infection. Therefore it is difficult to interpret a positive PCR result. NAATs are less valuable for the more rapidly growing mollicutes, *M. hominis* and *Ureaplasma* spp., than the more difficult to isolate *M. pneumoniae* and *M. genitalium*. At least four NAATs for mollicutes have U.S. Food and Drug Administration approval. The BioFire Diagnostics (Salt Lake City, UT) FilmArray RP (respiratory panel) detects nucleic acid from 14 respiratory pathogens, including *M. pneumoniae*, in nasopharyngeal swabs.

Culture

Because recovery from culture is difficult (sensitivity approximately 40%), isolation of *M. pneumoniae* from respiratory sites is infrequently attempted. Growth may take several weeks, and technical expertise is necessary. *M. hominis* and *Ureaplasma* spp. are less stringent in their growth requirements

Table 25.5 Major clinical and corresponding diagnostic manifestations of *Mycoplasma pneumoniae*

Manifestation	Days after onset						
	5	10	15	20	25	35	40
Headache and malaise	+ 1	+ 3	+ 3	+ 2	+ 1		
Dry cough	+ 2	+ 4	+ 4	+ 1

Fever							
With antimicrobial treatment	104° F	104° F	102° F	100° F	Absent		
Without antimicrobial treatment	104° F	100° F	Absent	Absent	Absent		
Chest radiography	+ 2	+ 3	+ 2	+ 2	+ 1		
<i>Mycoplasma</i> culture with or without antimicrobial treatment	+	+	+	+	+	+	
Complement fixation (titer)	≤8	8	32	64	256	256	128
<i>Mycoplasma</i> -specific Ig							
IgM	–	+	+	+	+	+	+
IgG	–	–	+	+	+	+/–	–

+ 4, Most severe; + 1, least severe; +, present or positive; –, absent or negative; IgG, immunoglobulin G; IgM, immunoglobulin M.

but require cholesterol for synthesis of plasma membranes. *M. hominis* is the only species that will grow on sheep blood and chocolate agars. Diagnosis of *M. pneumoniae* infection is usually established serologically, traditionally with acute-phase and convalescent sera collected 2 to 3 weeks apart to demonstrate a fourfold increase in titer. A representation of classic clinical and corresponding diagnostic manifestations of *M. pneumoniae* is shown in Table 25.5. As noted, many of the early symptoms are nonspecific, and a thorough understanding of the disease process is necessary for interpretation of serum and culture results.

Media

Several media have been developed for the recovery of mollicutes, and no single medium is suitable for all species isolated from humans. Penicillin can be added to minimize bacterial contamination. *M. hominis* and *Ureaplasma* spp. are more rapid growers and relatively easy to recover compared with the other mollicutes. SP4 broth and agar are ideal for *M. pneumoniae* and *M. hominis*. *M. pneumoniae* and *M. genitalium* require glucose (their major energy source), *M. hominis* requires arginine, and *Ureaplasma* spp. require urea. *Ureaplasma* spp. also require media to have a pH near 6.0 (Shepherd 10B arginine broth) with a buffer to maintain the pH. It is difficult to sustain *Ureaplasma* spp. in culture because death occurs rapidly when the urea is depleted, and the bacteria are sensitive to changes in pH because of urea utilization. *M. hominis* and *U. urealyticum* require cholesterol for synthesis of plasma membranes and other undetermined growth factors; fetal calf serum (20% vol/vol) is the traditional nutrient source. A8 agar can be used as a solid medium to recover *M. hominis* and *Ureaplasma* spp. Because mycoplasmas do not produce turbidity in broth media, a pH indicator, such as phenol red, should be added to detect growth.

Recovery of mycoplasma from blood can be performed by placing uncoagulated blood into mycoplasmal broth media. A ratio of 1:10 (blood to broth) and 10 mL of blood for adults is recommended. Sodium polyanethol sulfonate (SPS), an

additive often found in commercial blood culture media, is inhibitory to mycoplasma. The addition of 1% (weight per volume) gelatin might help overcome the inhibitory effect of SPS. Nevertheless, the use of commercial blood culture media, whether or not used in automated instruments, is not recommended. Fig. 25.5 presents a schematic representation of media and methods used in the traditional procedures for isolation and identification of *Mycoplasma* spp.

Fluids should be centrifuged and the pellet resuspended in a small volume of liquid for inoculation of media. It is important that specimens be diluted in broth up to 10⁻³ before each dilution is plated. This helps minimize the inhibitory effects of antimicrobial agents, antibodies, and other antibacterial factors that might be present in the specimen.

Commercial culture media and kits for the detection and recovery of mollicutes have been developed and are available in the United States and Europe. Such products may detect, quantify, identify, and determine the antimicrobial susceptibility of genital mycoplasmas from urogenital specimens and *M. pneumoniae* from respiratory secretions. These kits are useful in laboratories that infrequently perform cultures for the mollicutes, but laboratory scientists must be aware of the limitations of these assays and perform internal quality control.

Isolation and identification

Once inoculated, broth media should be placed at 35° C under atmospheric conditions, whereas solid agar media may be incubated in an environment of room air enhanced with 5% to 10% carbon dioxide (CO₂) or in an anaerobic atmosphere of 95% nitrogen gas (N₂) with 5% CO₂. *M. hominis* and *Ureaplasma* spp. colonies may appear within 2 to 4 days, whereas *M. pneumoniae* colonies may take 21 days or longer. *Mycoplasma*-like colonies are stained with Dienes or methylene blue stain. Staining is performed by placing a small block of the agar on a glass slide, covering the colony with the stain, adding a coverslip, and examining the agar microscopically under low power. *M. hominis* has a typical “fried egg” appearance, with

*SP4 is sucrose phosphate buffer, Mycoplasma base, fetal bovine serum (20%), phenol red. Medium stabilizes and decontaminates specimen. Storage at -70°C for repeated testing is recommended.

†Thin colony periphery. Examine with stereomicroscope using $\times 20$ to $\times 60$ magnification.

‡Color change: positive, yellow color with no gross turbidity; negative, red color.

§Guinea pig red blood cell hemadsorption (GP-RBC-HAD). β -Hemolysis test for presumptive identification of *Mycoplasma pneumoniae* may be used in lieu of GP-RBC-HAD.

Note: Methylene blue or Dienes stain can be used for detection of *Mycoplasma* spp. on SP4 agar; plate immunofluorescence using labeled antibody and nucleic acid amplification can be used for identification.

Fig. 25.5 Flow diagram for *Mycoplasma* spp. isolation using classic traditional methods.

the periphery staining a light blue and the center dark blue (Fig. 25.6). *Mycoplasma* spp. almost universally show a mixed colony presentation on primary isolation when examined with a stereomicroscope (Fig. 25.7).

Ureaplasma spp., once called **T-strain mycoplasma** (*T* for "tiny"), form extremely small colonies that are difficult to see with the naked eye; hence, mycoplasmal cultures on solid media should always be examined with a stereomicroscope. Fig. 25.8 shows *M. hominis* and *U. urealyticum* grown on New York City agar. Urease activity of *Ureaplasma* may be detected on solid agar containing urea and manganese chloride (U9B urease color test medium). Urease-positive colonies are a dark golden-brown color because of the deposition of manganese dioxide.

Although uncommon, extragenital *M. hominis* infections are emerging. This organism should be considered whenever many polymorphonuclear cells are seen on Gram stain, but

Fig. 25.6 Dienes stain of *Mycoplasma* spp. colonies demonstrating typical fried egg appearance ($\times 40$).

Fig. 25.7 Typical mixed sizes of *Mycoplasma* spp. on primary isolation media, *Mycoplasma salivarium* ($\times 20$). (Courtesy Bionique Testing Laboratories, Saranac Lake, NY)

Fig. 25.8 Mixed isolation of *Mycoplasma hominis* and *Ureaplasma urealyticum* showing why *U. urealyticum* was originally called T-strain mycoplasma, T for "tiny" (arrow) ($\times 40$).

there is no growth on routine bacterial culture. *M. hominis* grows well anaerobically and will appear as pinpoint (0.05-mm), clear, glistening, raised colonies on Columbia colistin-nalidixic acid agar or anaerobic blood agar (Centers for Disease Control and Prevention formula) in 48 hours. Under anaerobic conditions, the colonies do not display the "fried egg" morphology. The anaerobic plate should be examined by using oblique light. The colonies that do not take up Gram stain should be subcultured to A7 medium, on which they demonstrate typical "fried egg" growth and stain positive with Dienes or methylene blue stain if they are *Mycoplasma* spp.

Although not conclusive, growth rate, body site recovered from, and colony appearance can aid in the identification of *Mycoplasma*. Glucose utilization in SP4 broth will cause an acid shift producing a yellow color, whereas arginine metabolism will produce an increase in pH, changing the indicator to a deeper red color. In 10B broth, urea or arginine utilization will increase the pH, changing the pH indicator from orange to deep red. A slow-growing mycoplasma from a respiratory specimen producing a yellow color in SP4 broth is likely *M. pneumoniae*. Production of an alkaline reaction in 10B broth after overnight incubation of a urogenital specimen is suggestive of *U. urealyticum*, whereas an alkaline shift in media with arginine within 24 to 72 hours is likely caused by *M. hominis*.

Case check 25.2

In the Case in Point, an infection caused by *U. urealyticum* would produce an alkaline shift in media containing urea in about 24 hours. If the infection was caused by *M. hominis*, an alkaline shift would occur in media containing arginine in 24 to 72 hours.

Previously, identification of the mollicutes was often done by typing methods using monoclonal antibodies and immunofluorescence and observation of plate media with a stereomicroscope. A direct plate immunofluorescent method also can be used. Fluorescent-labeled, anti-*M. pneumoniae* antibody is flooded on colonies on the plate; the plate is then washed and examined for immunofluorescence. The characteristic of guinea pig red blood cells (0.4% in saline) adhering to colonies of *M. pneumoniae* and not *M. hominis* is another standard assay that helps distinguish the two species. Furthermore, guinea pig cells do not adhere to large-colony *Mycoplasma* spp., which are common inhabitants of the upper respiratory tract. PCR-based assays are now commonly used because they are widely available, less subjective, and easier to perform. Matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry was shown to identify most human mollicute species. However, testing requires 30 mL to 100 mL of culture for the mollicutes, limiting the use of this method.

Serologic diagnosis

Because of the inherent difficulties of cultures and interpretations of a positive PCR assay result, *M. pneumoniae* has historically been diagnosed by serologic methods. Optimally, serum samples for serologic testing should be collected at the onset of symptoms and 2 to 3 weeks later for acute-phase and convalescent measurements. This delay in testing is an obvious drawback. However, using a single immunoglobulin M (IgM) determination is flawed. Some individuals, especially those older than 40 years of age, might not produce IgM, possibly due to previous exposure. In addition, IgM antibody can persist for weeks to months.

M. pneumoniae induces the formation of autoantibodies that bind to a number of antigens on host cells, including the I antigen found on human red blood cells. Because they agglutinate type O Rh-negative erythrocytes at temperatures below normal body temperature (optimal is 4° C), anti-I antibodies are referred to as *cold agglutinins*. The cold agglutinin antibody titer was used for many years as an indicator of primary atypical pneumonia, but it is insensitive and nonspecific for *M. pneumoniae*. Approximately 50% of patients with primary atypical pneumonia produce a detectable cold agglutinin antibody titer. This assay is no longer recommended for the diagnosis of *M. pneumoniae* infection.

Previously, the most used technique for demonstration of *M. pneumoniae*-specific antibodies was the complement fixation assay, which was time-consuming and had inherent technical problems. The assay also suffered from false-positive results caused by autoantibodies and cross-reactivity to *M. genitalium*. Several commercially available enzyme immunoassays and immunofluorescence assays are now available for the detection of serum antibodies and, in some cases,

detect IgM or IgG. Table 25.6 highlights selected features of these immunologic assays and other methods. It is important to remember that demonstration of a significant increase in antibody titer in conjunction with culture isolation is preferable for a definitive diagnosis. Serologic methods are available for *M. hominis* and *U. urealyticum* but are generally performed only by reference laboratories and are not recommended for routine diagnosis.

Antimicrobial susceptibility

The mollicutes are inherently resistant to the β -lactams (penicillins and cephalosporins) as well as sulfonamides, trimethoprim, and rifampin because they lack a cell wall. *M. pneumoniae* has remained susceptible to the tetracyclines, newer fluoroquinolones, and the macrolides (e.g., erythromycin). However, there have been scattered reports of high-level macrolide resistance. Roughly 15% of United States isolates are macrolide resistant. Because of side effects, tetracycline is used only for the treatment of adults. *M. hominis*, which is more resistant than *M. pneumoniae*, is usually resistant to erythromycin but susceptible to clindamycin and lincomycin, whereas *U. urealyticum* is generally resistant to clindamycin and lincomycin and susceptible to erythromycin. Both organisms are often susceptible to tetracycline, but high-level resistance is emerging and is common in some geographic areas.

Standard minimal inhibitory concentration methods for susceptibility testing by broth microdilution and agar dilution of mycoplasma have been established by the Clinical and Laboratory Standards Institute. The agar dilution method is regarded as the reference method; however, because of the high degree of technical expertise required and the few mollicute isolates, this assay is not offered by most hospital laboratories. The broth microdilution is the most used method to determine the minimal inhibitory concentration. With antimicrobial resistance increasing, the availability of newer broad-spectrum antimicrobials, and the emergence of more

infections caused by *Mycoplasma* spp., antimicrobial susceptibility testing methods are becoming more important. Because of the variable susceptibility pattern of *M. hominis*, antimicrobial susceptibility testing is usually recommended for clinically significant isolates. These isolates should be forwarded to a reference laboratory for testing.

Historically, *M. pneumoniae* had a predictable sensitivity pattern, so antimicrobial susceptibility testing was not often warranted. However, with high-level macrolide resistance increasing, molecular assays were developed to detect mutations in 23S rRNA that results in macrolide resistance. These assays can be performed directly on clinical specimens eliminating the need for cultures to isolate the organism.

Interpretation of laboratory results

M. pneumoniae detected by any method from pulmonary or nonpulmonary specimens should be considered significant and a pathogen. The high sensitivity of the PCR assay means that a positive result must be correlated with the clinical picture. Interpretation of *M. hominis* isolation is not as obvious; differentiation from colonization and infection requires detailed clinical analysis and potentially repeated cultures. Isolation from a normally sterile site is significant.

U. urealyticum is the most difficult to assess clinically. In urogenital specimens, it has been reported to colonize up to 70% of men and 45% of women with no apparent infection. Its isolation is not indicative of pathogenicity, and it is incumbent on the laboratory to educate the health care provider. Culture results should include a statement suggesting its potential for colonization versus pathogenicity. In these specimens, quantification is important. In sterile specimens, particularly CSF isolates, it is reasonable to assume that isolation is significant.

Respiratory specimens received in the laboratory often provide limited clinical information. Specimens are processed and inoculated onto the appropriate media given the

Table 25.6 Comparative features of various laboratory methods used to detect *Mycoplasma pneumoniae*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*

Detection method	<i>Mycoplasma pneumoniae</i>	<i>Mycoplasma hominis</i>	<i>Ureaplasma urealyticum</i>
Nonserologic			
Culture	Traditionally difficult	Method of choice, but must differentiate infection from colonization	Method of choice using urease detection, but must differentiate infection from colonization

Table 25.7 Laboratory detection of frequent respiratory pathogens

Epidemiologic factors				Laboratory methods			
Age	Organism Frequently Involved	Disease	Season	Specimen Source	Stain	Culture	Nonculture
Newborn	1, 3, 4, 7	Pneumonia	Year round ^a	Tracheal suction	Gram	Routine, plus mycoplasmal	
Grade school	2, 4	Atypical pneumonia	Fall and winter	Sputum, nasopharynx	Gram	Routine, plus mycoplasmal	Mycoplasma serology
College student	1, 2, 8	Biphasic disease with pharyngitis and later, bronchitis	Year round ^b	Sputum, nasopharynx	None ^c	<i>B. pertussis</i>	Mycoplasma serology
Adult	2, 4, 5, 6	Pneumonia or atypical pneumonia	Year round ^a	Sputum	Gram	Routine	Mycoplasma serology
				Bronchoalveolar lavage specimen	Gram, Gomori methenamine silver, and/or calcofluor white	Routine, plus fungal	

1, *Chlamydia pneumoniae*; 2, *Mycoplasma pneumoniae* (outbreak); 3, *Mycoplasma hominis*; 4, viral, e.g., adenovirus, respiratory syncytial virus, influenza virus (seasonal); 5, other—fungus, *Legionella*, or *Pneumocystis pneumoniae*; 6, *Streptococcus pneumoniae*; 7, *Streptococcus agalactiae*; 8, *Bordetella pertussis*.

^aSeasonal incidence depends on the pathogen.

^bThe greatest seasonal incidence of pertussis is spring and summer, followed by winter.

^cIn place of direct stains, nucleic acid amplification tests for *C. pneumoniae* and/or *B. pertussis* should be performed.

most likely candidate for the disease, clinical presentation, age of the patient, and seasonality, recognizing that there is a certain predictability with selected pathogens. Table 25.7 presents laboratory methods used to diagnose infections caused by several pathogens—*Mycoplasma*, *Chlamydia*, *Legionella*, mycobacteria, fungi, and viruses—in various age groups. All respiratory specimens should be stored at -80°C if storage time is likely to exceed 24 hours. Acute-phase sera should also be stored frozen for subsequent antibody titer testing.

POINTS TO REMEMBER

- The mollicutes are minute organisms characterized by the lack of a cell wall. Because of the lack of a cell wall, the mycoplasmas are inherently resistant to the β -lactam antibiotics.
- The most clinically significant species of the Mycoplasmataceae are *M. pneumoniae*, *M. hominis*, *M. genitalium*, *M. fermentans*, and *Ureaplasma* spp., although others are beginning to be recognized as opportunistic pathogens.
- M. pneumoniae* is an important cause of community-acquired, atypical pneumonia. It is not considered part of the normal human microbiota.
- M. hominis*, *M. genitalium*, and *Ureaplasma* spp. are genital mollicutes.
- Because of the difficulty to isolate, *M. pneumoniae* infection is most often diagnosed by serologic methods. *M. hominis* and *Ureaplasma* spp. are commonly diagnosed by culture, although PCR technology is also available. *M. genitalium* and *M. fermentans* are generally detected by PCR.

LEARNING ASSESSMENT QUESTIONS

- From which source did the neonate described in the Case in Point likely acquire the infection?
 - Breast milk
 - Inhalation after birth
 - Passed through the birth canal
 - Infectious agent crossed the placenta
- Why was the Gram stain result negative in the Case in Point?
 - Mollicutes do not Gram stain.
 - The Gram stain is too insensitive.
 - Mollicutes do not retain safranin; need to use a different counterstain.
 - When mollicutes are suspected, the time needed to heat fix the smear must be extended.
- How does primary atypical pneumonia caused by *M. pneumoniae* differ from pneumonia caused by *S. pneumoniae*?
 - Has a lower mortality rate
 - Is not spread person to person
 - Is seen more often in older adults
 - Is characterized by a bloody, productive cough
- Which special stain is used on suspected colonies of *Mycoplasma*?
 - Acridine orange
 - Calcofluor white
 - Dienes
 - Silver
- An amniotic fluid is submitted to the microbiology laboratory for isolation of mycoplasma. It will be 48 hours before the specimen can be processed. At what temperature should the specimen be stored?

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Compare the general characteristics of mycobacteria with those of other groups of bacteria.
2. Discuss the clinical disease caused by *Mycobacterium tuberculosis*.
3. Analyze patient results obtained with the tuberculin skin test and interferon-gamma release assay for the diagnosis of tuberculosis.
4. Develop a protocol for the isolation and identification of *M. tuberculosis* from a sputum specimen.
5. Discuss the clinical significance of nontuberculous mycobacteria.
6. Describe the appropriate specimen collection and processing procedures to recover mycobacteria from clinical samples.

7. Discuss the safety precautions to be followed while working in a mycobacteriology laboratory.
8. Justify the digestion and decontamination requirements of certain clinical specimens for the isolation of mycobacteria.
9. Describe the principles and procedures for the stains used to demonstrate mycobacteria in clinical samples and culture isolates.
10. Compare the different culture media used for the isolation of mycobacteria.
11. Discuss the different tests used to identify mycobacteria.
12. Compare continuous monitoring systems with those of conventional media for detecting mycobacterial species in clinical samples.

Ziehl-Neelsen stain

Case in point

A 56-year-old male patient came to the emergency department complaining of fatigue and weight loss (10 lb) over the past 12 months. The patient also complained of a cough for 3 months that produced red-tinged sputum. He indicated a history of night fever and chills but reported not having dyspnea or chest pain. The patient, who moved to the United States from Mexico, had a family history of pulmonary tuberculosis. He reported that his last purified protein derivative (PPD) skin test, performed approximately 5 years ago, was nonreactive. Vital signs included temperature of 36.5° C (97.7° F), pulse of 63 beats per minute, respirations of 15 breaths per minute, and

blood pressure of 96/56 mm Hg. Chest radiography revealed an infiltrate in the upper lobe of the right lung. Computed tomography of the chest showed a nodular patchy opacity in the upper lobe of the right lung. The patient was admitted for further evaluation. A PPD skin test showed a 10-mm by 7-mm induration. Three sputum samples were obtained over a 3-day period for acid-fast bacilli (AFB) smear and culture. All three samples were reported as no AFB seen on direct acid-fast stained smears. Processed samples were inoculated onto Löwenstein-Jensen (LJ) medium and into BACTEC 12B bottles (BD Diagnostic Systems, Sparks, MD). After 12 to 14 days of incubation, the BACTEC bottles from all three specimens were positive. Kinyoun staining of smears from the bottles revealed AFB. Polymerase chain reaction (PCR) DNA amplification for *Mycobacterium tuberculosis* of the BACTEC medium showed a positive result. A four-drug antituberculosis regimen comprising isoniazid, rifampin, pyrazinamide (PZA), and ethambutol was recommended.

Issues to consider

After reading the patient's case history, consider:

- Significant aspects of this patient's family history
- The characteristic symptoms of tuberculosis
- The typical length of time for a culture to yield pathogenic *Mycobacterium*

The genus *Mycobacterium* is composed of over 180 recognized and proposed species. The most familiar of the species are *Mycobacterium tuberculosis* and *Mycobacterium leprae*, the causative agents of tuberculosis (TB) and Hansen disease (leprosy), respectively. Both diseases have long been associated with chronic illness and social stigma. TB remains a major cause of morbidity and mortality in the world today and is the leading cause of death resulting from a single infectious agent—surpassing human immunodeficiency virus (HIV). In 2020, The *Global Tuberculosis Report* by the World Health Organization (WHO) estimated 9.9 million new cases, and 1.5 million people died from TB, including 214,000 people with HIV worldwide.

Nontuberculous mycobacteria (NTM)

In addition to TB and Hansen disease, *Mycobacterium* spp. produce a spectrum of infections in humans and animals. A large group of mycobacteria, excluding the *M. tuberculosis* complex (MTBC) and *M. leprae*, normally inhabit the environment and can cause disease that often resembles TB in humans. These organisms are sometimes referred to as *atypical mycobacteria*, **nontuberculous mycobacteria (NTM)**, or *mycobacteria other than the tubercle bacillus (MOTT)*. The term *nontuberculous mycobacteria* is used here. The growing number of immunocompromised individuals worldwide has led to a resurgence of TB and diseases caused by NTM. Box 26.1 shows the usual clinical significance of *Mycobacterium* spp. isolates.

Epidemiologic changes have led to challenges in the mycobacteriology laboratory, including rapid identification of all clinically significant mycobacteria and antimicrobial susceptibility testing of *Mycobacterium* spp. Fortunately, new developments in the field of clinical mycobacteriology are helping meet these challenges. Rapid methods, like nucleic acid amplification tests (NAATs), can eliminate the need for lengthy culturing and protracted biochemical methods of identification. Further developments in the application of molecular biology, including matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry

General characteristics

Mycobacteria are slender, slightly curved or straight, rod-shaped organisms 0.2 to 0.6 μm $\times$ 1 to 10 μm in size. They are nonmotile and do not form spores. However, limited studies claim to demonstrate spores or sporelike structures in *Mycobacterium marinum*. The cell wall has extremely high lipid (mycolic acid) content; thus mycobacterial cells resist staining with commonly used basic aniline dyes, such as those used in Gram stain, at room temperature. Mycobacteria take up dye with increased staining time or application of heat but resist decolorization with acid-ethanol. This characteristic, referred to as acid fastness—hence the term *acid-fast bacilli* (AFB)—distinguishes mycobacteria from most other genera. Mycolic acids are also found in other genera (e.g., *Corynebacterium* and *Rhodococcus*); however, the amount of mycolic acids in the mycobacteria is much larger than in these other bacteria.

Mycobacteria are strictly aerobic, but increased carbon dioxide (CO₂) concentration will enhance the growth of some species. The pathogenic mycobacteria grow more slowly than most other bacteria that are pathogenic to humans. Typically, mycobacteria associated with disease require 2 to 6 weeks of incubation on complex media at specific optimal temperatures, whereas the rapidly growing species generally grow on simple media in 2 to 3 days at temperatures of 20° to 40° C. One of the mycobacteria pathogenic to humans, *M. leprae*, fails to grow in vitro.

Clinical significance of the *Mycobacterium tuberculosis* complex

The *Mycobacterium tuberculosis* complex (MTBC) consists of *M. tuberculosis*, *M. bovis* (including the vaccination strain bacillus Calmette-Guérin [BCG]), *M. africanum*, *M. microti*, *M. canettii*, *M. caprae*, *M. pinnipedii*, *M. mungi*, *M. orygis*, *M. mungi*, and *M. suricattiae*. Members of the MTBC display a high degree of genetic homogeneity, although they have different phenotypic characteristics and mammalian host ranges. Within this group, most human infections are caused by *M. tuberculosis* and to a lesser extent *M. bovis* and *M. africanum*. *M. bovis* is found primarily in cattle, but it can infect other mammals, including humans. *M. africanum* has been associated with human cases of TB in tropical Africa, and *M. microti* has been linked to TB in both immunocompetent and immunocompromised individuals. *M. canettii* has been reportedly causing infections in children and patients with HIV infection in Africa. The remaining species are infrequently associated with human infections.

Mycobacterium tuberculosis

Mycobacterium tuberculosis was first described by Robert Koch in 1882. However, TB is one of the oldest documented communicable diseases and remains a leading cause of morbidity and mortality globally. A disease of poverty, as many as 25% of the world's population may be infected with the bacteria causing TB. About 90% of TB cases occur in 30 TB high-burden countries. The geographic areas with the most cases are Southeast Asia (44%), Africa (25%), and the Western Pacific (18%). The United States has one of the lowest TB rates in the world. In 2021, 7860 TB cases were reported, 687 more than during 2020 (7173), a 9.4% increase in TB incidence (cases per 100,000 population) from 2.16 to 2.37. However, up to 13 million people living in the United States have latent TB infection. These individuals are infected with the bacteria causing TB but remain asymptomatic. Currently, about 71% of the cases are in foreign-born individuals from endemic areas.

Primary tuberculosis

After exposure to *M. tuberculosis*, whether or not a person develops TB is determined by his or her cellular immune response, the infective dose, and the virulence of the strain. TB is usually a disease of the lower respiratory tract. Typical signs and symptoms include malaise, weight loss, night sweats, and cough that can produce or not produce sputum that is with or without blood. Tubercle bacilli are acquired

from persons with active disease who are excreting viable bacilli by coughing, sneezing, or talking. Airborne droplets containing bacteria enter the respiratory tract of an exposed individual and reach the lung alveoli. *M. tuberculosis* cells are phagocytized by alveolar macrophages but can prevent fusion of phagosomes containing bacteria with lysosomes. This permits intracellular multiplication of the bacteria. In a person with adequate cellular immunity, macrophages secrete interleukin-12 and tumor necrosis factor alpha, which recruit T cells and natural killer cells and enhance the inflammatory reaction. Some of the T cells differentiate into T-helper cells type-1 (Th1) releasing lymphokines, such as interferon-γ (IFN-γ). IFN-γ stimulates macrophages in the infection site to destroy intracellular mycobacteria. This is followed by regression and healing of the primary lesion.

In many exposed individuals, the immune system does not initially eliminate the bacteria, and this can result in life-long or latent infections. The pathologic features of TB are the result of a hypersensitivity reaction to mycobacterial antigen. If there is little antigen and a strong hypersensitivity reaction, a small, hard tubercle, or granuloma, may be formed. The granuloma is an organization of lymphocytes, macrophages, fibroblasts, and capillaries, along with fibrosis encapsulation. With granuloma formation, the bacteria are contained and can ultimately be killed, and healing occurs along with calcification and scar formation as a reminder of the past infection.

If the antigen load and hypersensitivity reaction are both high, tissue necrosis from the enzymes of degenerating macrophages can occur; the tissue response is less organized, and granulomas are surrounded by fibrin that protects the bacteria from phagocytosis by macrophages. Necrotic or caseous material can be present at the site of the primary lesion because of solid or semi-solid amorphous material deposited at the site of necrosis. After healing of the primary infection, the bacilli are not totally eradicated but can remain viable, but dormant, in granulomas for months or years. In infected individuals, there is a potential for reactivation of TB when the bacteria are released from the granulomas. This happens because of immunosuppression from old age or other causes.

A small percentage of individuals who are infected with TB develop progressive (active) pulmonary disease, usually from a failed cellular immune response and, hence, a failure to stop multiplication of the bacilli. In young children or older adults with primary infection and in people with an underlying immunodeficiency, massive lymphohematogenous dissemination may occur and lead to meningeal or miliary (disseminated) TB, which is discussed later. In addition, 10% of young adults may progress to active disease from their primary infection. This will resemble reactivation TB in older adults; the only way to differentiate it is a positive purified protein derivative (PPD) skin test result in a previously negative individual.

Case check 26.1

A positive PPD skin test result only indicates past exposure to *M. tuberculosis*; it does not imply a recent infection. In the Case in Point, the patient reported a negative skin test result obtained about 5 years ago, thus establishing a negative baseline. During his current evaluation, he had a positive skin test result, indicating exposure and subsequent immune response at some point in the past 5 years.

Reactivation tuberculosis

Approximately 5% of those infected develop active disease within 5 years, and an additional 5% to 10% develop disease within their lifetime. Progression from infection to active disease differs, depending on the patient's age and the intensity and duration of exposure. Malnutrition, with or without other factors, such as alcoholism, homelessness, incarceration, immunosuppression, and HIV infection, can contribute greatly to progression to active TB. Reactivation TB also occurs more frequently in patients with **immune-mediated inflammatory diseases like systemic lupus erythematosus and rheumatoid arthritis**.

Reactivation TB from a latent infection occurs when there is an alteration or suppression of the cellular immune system in the infected host that favors replication of the bacilli and progression to disease. The symptoms of **disease are slow in developing (insidious) and consist of fever, shortness of breath, night sweats and chills, fatigue, anorexia, and weight loss**. About 20% of individuals may have no symptoms, but most patients eventually have productive cough, chest pain, and fever. Hemoptysis, indicating cavitation and necrosis, occurs in 25% of cases. In patients with reactivation TB, radiography reveals a patchy or confluent consolidation with increased linear densities extending to the hilum; thick-walled cavities without air-fluid levels usually are found in the apical or posterior segments of the upper lobe or in the superior segment of the middle lobe of the lung. If there is bronchogenic spread of the bacilli, multiple alveolar densities will be seen; rarely is there enlargement of the lymph nodes.

In chronic disease, fibrosis, loss of lung volume, and calcifications will be demonstrated. **The PPD skin test may yield negative results in up to 25% of these cases; diagnosis is confirmed by stained smear and culture of sputum, gastric aspirates, or bronchoscopy specimens**. Fiberoptic bronchoscopy has been found to yield 95% recovery of the bacteria; postbronchoscopic sputa are also usually positive. In any case of pulmonary TB, complications could occur if diagnosis and treatment are delayed. These include empyema, pleural fibrosis, massive hemoptysis, adrenal insufficiency (rare), and hypercalcemia (up to 25% of cases). In patients with acquired immunodeficiency syndrome (AIDS) and TB with drug-resistant bacilli, the risk of progression to disease from infection is quite high, although clinical findings may differ from those in the patient with AIDS and reactivation TB. The diagnosis is usually made by stained smears and culture, with a rate of sensitivity similar to that in patients without AIDS.

Extrapulmonary tuberculosis

Disseminated or extrapulmonary tuberculosis (EPTB), infection outside the lungs, occurred much less commonly than pulmonary TB before the AIDS epidemic. In the WHO's 2020 *Global Tuberculosis Report*, extrapulmonary TB represented 16% of the 7.1 million incident cases. **It has been suggested that an increased prevalence of risk factors for EPTB, such as HIV infection, foreign-born status, and advanced age of the population, has contributed to an increased** proportion of EPTB cases in the United States.

The association between HIV infection and overall TB cases is well characterized, but the relationship between EPTB and HIV infection is less clear. EPTB is a relatively common presentation in individuals with HIV infection, although pulmonary

disease is most often associated with HIV infection. Risk factors for EPTB are not clear. Some studies have indicated that besides HIV positivity, patients with liver cirrhosis and diabetes are also at increased risk. Genetic descent (e.g., Asia Pacific and Native American) has been proposed as a risk factor as well.

Miliary tuberculosis refers to the seeding of many organs outside the pulmonary tree with AFB through hematogenous spread. This usually occurs shortly after primary pulmonary disease but can take place at any point during acute or chronic TB. The most common sites of spread of *M. tuberculosis* are the lymph nodes, spleen, liver, lungs, bone marrow, and kidneys. Other forms of EPTB include pleuritis, lymphadenitis, meningitis, peritonitis, and gastrointestinal and skeletal infections. Almost any organ of the body can be infected by *M. tuberculosis*. However, diagnosing EPTB is challenging because clinical samples must be obtained from relatively inaccessible sites, and often only a few bacteria are present, thus decreasing the sensitivity of diagnostic tests.

Overall, children account for most cases of miliary TB, but it is also a common form of TB in individuals with HIV infection. The mortality is 20% or higher in most studies; the finding of meningitis is an extremely poor prognostic indicator. Up to 70% of patients with HIV infection may have EPTB alone or, usually, in combination with pulmonary disease. The most common extrapulmonary sites in this population are the lymph nodes (especially mediastinal), **genitourinary tract, and abdominal cavity**. Bacteremia is not uncommon.

Lymphadenitis is usually a disease of children, appearing as painless head or neck swellings. Genitourinary TB can involve the kidneys and genital organs. Renal TB accounts for 2% of all cases of TB and manifests itself as typical urinary tract symptoms and sterile pyuria. Cultures may be positive in up to 80% of cases. Male genital TB usually appears as a scrotal mass and frequently occurs along with renal TB. Skeletal TB of the spine is referred to as Pott disease. Back pain is the most common characteristic. Cultures of bone and tissue are needed to confirm the diagnosis. Peripheral skeletal bones and joints also may be involved, with the hip and knee being the most common sites.

Meningitis caused by *M. tuberculosis* is usually the result of a rupture of a tubercle into the subarachnoid space and not usually via hematogenous spread. In childhood, it occurs rarely after primary pulmonary infection. Most infections occur at the base of the brain; patients may develop very thick, gelatinous, masslike lesions there. With more chronic disease, a fibrous mass may surround cranial nerves. Involvement of arteries can cause infarctions. Cerebrospinal fluid (CSF) examination usually reveals an elevated protein level, a decreased glucose level, and a predominance of lymphocytes.

Diagnosis of *Mycobacterium tuberculosis* infection

Diagnosis of primary TB is usually limited to signs and symptoms, chest roentograph, and a positive PPD skin test or interferon-gamma release assay (IGRA) result. Cultures are confirmatory, but because of the slow-growing nature of *M. tuberculosis*, a culture result can take up to 8 weeks. Children may demonstrate a nonproductive cough and fever, with or without shortness of breath; these symptoms are unusual in adults. Chest radiography usually shows normal results, although, rarely, there may be infiltrates without cavitation in the anterior segment of the upper, middle, or lower lobe,

with hilar or paratracheal lymphadenopathy. Along with these limited clinical findings, patients with primary TB can have a paucity of bacteriologic findings. If sputum or bronchial washings are cultured during the primary infection, the positivity rate is only 25% to 30%.

The tuberculin skin test has been used for many years to determine an individual's exposure to *M. tuberculosis*. Protein extracted and purified from the cell wall of culture-grown *M. tuberculosis* is used as the antigen (i.e., PPD). A standardized amount of antigen is injected intradermally into the patient's forearm. The skin test detects a patient's cell-mediated immune (CMI) response to the bacterial antigens in a type IV hypersensitivity reaction. Reactivity is read at 48 hours. In immunocompetent individuals, the presence of a raised firm area (induration) 10 mm or larger is considered reactive. A reactive tuberculin skin test only indicates past exposure to *M. tuberculosis*. Other *Mycobacterium* spp. generally result in an induration smaller than 10 mm. Immunocompromised patients with previous *M. tuberculosis* infection may also produce induration less than 10 mm. Some countries use attenuated *Mycobacterium bovis* (BCG) as a vaccine against TB. Individuals who have received this vaccine will have a reactive PPD skin test.

Because some people with latent TB infection have a negative reaction when tested years after being infected, the **two-step PPD skin test is often recommended**. First, a routine PPD skin test is administered. If the result is reactive, no additional skin testing is needed. If the result is nonreactive, a second PPD skin test is administered in 1 to 3 weeks. If the second test is also nonreactive, the individual is considered not infected. A reactive test indicates a boosted response for an infection many years ago. The individual should be evaluated to determine if treatment is necessary.

IGRAs have several advantages over skin testing and have become more frequently used. The Quantiferon-TB Gold Plus assay (Cellestis, Carnegie, Victoria, Australia) and the T-SPOT.TB (Oxford Immunotec, Oxford, England) measure the CMI response in whole-blood samples to mycobacterial antigens. These assays have a greater specificity than the PPD skin test and are just as sensitive if not more so. IGRAs have reported sensitivities and specificities of 88% to greater than 95%. Like skin testing, however, the sensitivities of IGRAs in children and those who are immunosuppressed, such as patients with AIDS, are lower compared with adults and immunocompetent persons.

Unlike the tuberculin skin test, IGRAs are not affected by BCG vaccination and do not cross-react with antigens from most other mycobacterial species. They are also free from the bias that might be associated with reading and interpreting the tuberculin skin test results. In addition, patients need to be seen only once by a health care provider and do not need to return, as is necessary for reading a tuberculin skin test. Results are available in about 24 hours. However, these tests are more expensive than tuberculin skin testing. Both IGRA methods measure IFN- γ production by T cells that have been stimulated by two or three secretory, low-molecular-weight mycobacterial peptides: early-secreted antigenic target 6 (ESAT-6), culture filtrate protein 10 (CFP-10), or TB 7.7. Like the tuberculin skin test, IGRAs cannot distinguish between active and latent infections.

Cultures, while time-consuming, have been considered the reference method for diagnosing most *Mycobacterium* infections. Isolation of mycobacteria is covered in more detail later

Fig. 26.1 *Mycobacterium tuberculosis* growing on Löwenstein-Jensen medium.

in this chapter. Colonies of the slowly growing *M. tuberculosis* are typically raised, with a dry, rough appearance. The colonies are nonpigmented and classically described as being buff colored (Fig. 26.1). Elaboration of cord factor can result in characteristic cord formation. Optimal growth occurs at 35° to 37° C. *M. tuberculosis* is characteristically positive for niacin accumulation, reduction of nitrate to nitrite, and production of catalase, which is destroyed after heating (heat-stable catalase negative). Isoniazid-resistant strains may not produce catalase at all. *M. tuberculosis* is inhibited by nitroimidazopyran or *p*-nitroacetylaminobenzoyl- β -propiophenone (NAP). This species can be distinguished from *M. bovis* by the inhibition of *M. bovis* by thiophene-2-carboxylic acid hydrazide (T2H) and pyrazinamidase activity.

Treatment

The treatment of TB involves the use of more than one antimycobacterial agent in two phases for 4, 6 or 9 months. Currently, 10 drugs are approved by the U.S. Food and Drug Administration (FDA) for treating TB. Typically, phase one (intensive phase) treatment of pulmonary TB disease involves 8 weeks of therapy with isoniazid, rifampin, pyrazinamide, and ethambutol. Phase two (continuation phase) treatment consists of isoniazid and rifampin for an additional 18 weeks. In most individuals, AFB are cleared from the sputum within the first 2 months.

Although people with latent TB infection are asymptomatic and cannot spread TB, the bacteria can reactivate and progress to active TB disease. Therefore not only should people with TB disease be treated but also those individuals with latent TB infection. An estimated 80% of the people in the United States who develop TB disease do so because of untreated latent TB infection. Several regimens are used to treat latent TB infection. Short-course, rifamycin-based, 3- or 4-month regimens are recommended. To insure patient compliance, the WHO and the Centers for Disease Control and Prevention (CDC) recommend directly observed therapy.

Multidrug-resistant Mycobacterium tuberculosis

Multidrug-resistant tuberculosis (MDR-TB) is defined as resistance to at least isoniazid and rifampin, drugs recognized as the primary treatments for drug-susceptible *M. tuberculosis*. The incidence of MDR-TB in the United States has remained relatively stable, around 1%, since 1996.

Within any population of *M. tuberculosis*, resistance to a single agent can develop at a fairly well-defined rate. For example, with isoniazid and streptomycin, the chance that a resistant isolate will develop is approximately 1 in 10^6 . The rate of spontaneous mutation of resistance to both drugs in one cell is the product of the rates of resistance to the individual drugs, or 1 in 10^{12} . In a patient with pulmonary TB, the pulmonary cavity may contain 10^7 to 10^9 bacterial cells. Random drug resistance has a good likelihood of developing when only one antimycobacterial agent is used or if the patient is receiving multidrug therapy and fails to complete the course of medication. Therefore combination therapy (i.e., two or more drugs) to treat mycobacterial infections is recommended.

Risk factors for drug resistance may include previous treatment for TB, residence in an area endemic for drug resistance, or close contact with an individual who has MDR-TB. Drug resistance is usually acquired by spontaneous mutations because of inappropriate use of antimicrobial agents to treat *M. tuberculosis* and lack of patient adherence. If adherence is an issue, directly observed therapy is recommended to ensure proper treatment. Otherwise, resistance may be assumed, and in vitro testing should be performed.

MDR-TB requires an extended treatment period compared with drug-susceptible isolates. Second-line anti-TB drugs may include a regimen of four or five drugs that include an aminoglycoside, fluoroquinolone, pyrazinamide, and cycloserine/terizidone, among others. With the numbers of cases of MDR-TB increasing worldwide, newer agents are being tested in vitro to determine their efficacy.

In 2016, the WHO estimated that 6.2% of MDR-TB cases were extensively drug-resistant tuberculosis (XDR-TB). The CDC defines XDR-TB as TB resulting from strains resistant to rifampin (MDR/RR-TB) and isoniazid plus any fluoroquinolone and at least one of three injectable second-line anti-TB drugs (i.e., amikacin, kanamycin, or capreomycin). In 2021, the WHO published a new definition of XDR-TB, which is "TB caused by *Mycobacterium tuberculosis* (*M. tuberculosis*) strains that fulfill the definition of MDR/RR-TB and which are also resistant to any fluoroquinolone and at least one additional Group A drug (Group A drugs are the most potent group of drugs in the ranking of second-line medicines for the treatment of drug-resistant forms of TB using longer treatment regimens and comprise levofloxacin, moxifloxacin, bedaquiline and linezolid)."

XDR-TB has been reported in all regions of the world but is most frequently found in countries of the former Soviet Union and in Asia. Because of the threat of MDR-TB and XDR-TB, it is important for laboratories to identify the *Mycobacterium* spp. rapidly and perform antimicrobial susceptibility testing so appropriate therapy can be administered as quickly as possible.

Vaccine

The BCG vaccine, an attenuated *M. bovis*, is used in many countries with endemic TB. The vaccine is more efficacious in preventing infection when administered to children compared with adults. However, the vaccine cannot be given to immunocompromised individuals, such as those with HIV infection. It is therefore unlikely to be useful in countries with a high prevalence of HIV infection. Individuals who have received the vaccine will have a positive tuberculin (PPD) skin test result.

Mycobacterium bovis

Mycobacterium bovis causes TB primarily in cattle but also in other ruminants, as well as in dogs, cats, swine, parrots, and humans. The disease in humans closely resembles that caused by *M. tuberculosis* and is treated the same way. In some areas of the world, a significant percentage of cases of TB are caused by *M. bovis*, but in the United States, the number of isolates of this organism is very low.

M. bovis is closely related taxonomically to *M. tuberculosis* and belongs to the *M. tuberculosis* complex. It grows very slowly on egg-based media, producing small, granular, rounded, nonpigmented colonies with irregular margins after 21 days of incubation at 37° C. On Middlebrook 7H10 medium, colonies resemble those of *M. tuberculosis* but are slower to mature. Most strains of *M. bovis* are niacin negative, do not reduce nitrate, and do not grow in the presence of 2 µg/mL T2H, characteristics that distinguish the species from most strains of *M. tuberculosis*.

Clinical significance of nontuberculous mycobacteria

Over 180 species of NTM are recognized, and about one half are classified as slowly growing. Most NTM are found in soil and water. They have been implicated as opportunistic pathogens in patients with underlying lung disease (e.g., cystic fibrosis, chronic obstructive pulmonary disease), immunosuppression, or percutaneous trauma. AIDS has contributed greatly to the incidence and awareness of NTM disease. Chronic pulmonary disease resembling TB is the usual clinical presentation associated with these organisms, although a few species are more often associated with cutaneous infections. Some species can be commensal inhabitants of humans; therefore their isolation must be evaluated with clinical history and presentation. NTM infections are not considered transmissible from person to person or animal to person.

Slowly growing species

Mycobacterium avium Complex

Epidemiology

Currently, 11 species belong to the *Mycobacterium avium* complex (MAC), with *Mycobacterium avium* and *Mycobacterium intracellulare* being the most common species isolated from humans. These organisms are common environmental saprophytes and have been recovered from soil, water, house dust, and other environmental sources. Certain areas, such as coastal marshes, have higher concentrations of the organism. Environmental sources, especially natural waters, seem to be the reservoir for most human infections.

M. avium is a cause of disease in poultry, cattle, and swine, but animal-to-human transmission has not been shown to be an important factor in human disease. The three subspecies found in animals are rarely associated with human infections; this may explain why animal-to-human transmission is uncommon. A fourth subspecies, *M. avium* subsp. *hominissuis*, is responsible for most human infections. MAC is the

leading causes of NTM infections in humans. A large increase in MAC infections occurred in the past primarily because of the increased number of infections in patients with AIDS. Although not a reportable disease, recently MAC infections have been decreasing among persons with HIV infection.

Clinical infections

Pulmonary disease resulting from MAC infection can have a variety of clinical presentations. The most common form is a slowly progressive, chronic cavitary disease in middle-age men with a history of smoking and other underlying pulmonary disease. The disease resembles the clinical picture of TB—cough, fatigue, weight loss, low-grade fever, and night sweats. Other presentations include lymphadenitis and tenosynovitis. Disseminated disease is common in immunocompromised patients, such as those with AIDS, or in patients with hematologic abnormalities. MAC infections are the most common systemic bacterial infection in patients with AIDS. The loss of CD4⁺ T cells reduces the activation of macrophages to kill MAC organisms. NTM pediatric lymphadenitis previously involved *M. scrofulaceum* in the 1970s; however, MAC has been associated in approximately 80% of recently reported cases.

The clinical outcome of MAC lung disease is unpredictable, so management of patients can be difficult. Observation, therapy for underlying pulmonary disease (e.g., bronchodilators, broad-spectrum antimicrobials, smoking cessation), and periodic sputum cultures may be all that is required for most patients. For patients with significant symptoms and advanced or progressive radiographic disease, multidrug therapy is indicated. For children with cervical lymphadenitis, excision surgery without chemotherapy is usually successful. A combination of surgical excision and chemotherapy is the usual treatment for adults with localized nonpulmonary disease. Most isolates of MAC are resistant to commonly used antimycobacterial drugs. However, many cases of disseminated disease in immunosuppressed patients without AIDS respond to multidrug regimens. Multidrug therapy consisting of clarithromycin or azithromycin along with ethambutol and rifampin has resulted in symptomatic reduction and clinical improvement in many, but not all, patients.

Laboratory diagnosis

Because the two most common human isolates in the MAC are so similar, most laboratories do not distinguish between them but report isolates of both species as MAC. On primary isolation media, these organisms grow slowly, producing thin, transparent or opaque, homogeneous smooth colonies. A small proportion of strains may exhibit rough colonies. Usually, the colonies are nonpigmented, but they may become yellow with age. Rarely are the colonies pigmented from the onset of detectable growth. The optimal growth temperature is 37° C.

On microscopic examination, the cells are short, coccobacillary, and uniformly stained, without beading or banding. Long, thin, beaded bacilli resembling *Nocardia* spp. may be seen in stains of very young cultures or under certain other conditions. MAC species are inactive in most physiologic tests used to identify the mycobacteria. Exceptions are the production of a heat-stable catalase and the ability to grow on media containing 2 µg/mL T2H. Nucleic acid probes are available for the identification of MAC and the two species. Nucleic acid probes for the identification of *M. avium* and *M. intracellulare* are commercially available. Phenotypic characteristics

are insufficient for species identification of the slowly growing mycobacteria. Molecular methods are now the reference method.

Mycobacterium avium subsp. *paratuberculosis*

Mycobacterium avium subsp. *paratuberculosis* (MAP) is the causative agent of Johne disease, an intestinal infection occurring as a chronic diarrhea in cattle, sheep, goats, and other ruminants. MAP has also been reported to cause a diarrheal/wasting disease in nonhuman primates. MAP is found in potable water, pasteurized milk, and other foods. Researchers have found a significantly higher percentage of anti-MAP antibodies in individuals with Crohn disease compared with individuals without irritable bowel disease. These studies suggest a link between MAP and Crohn disease. However, a causal relationship between the presence of MAP infection and autoimmune disease has not been demonstrated. MAP is difficult to cultivate because of its very slow growth rate (3 to 4 months) and its need for mycobactin-supplemented medium for primary isolation. Mycobactin is an iron-binding compound produced by other mycobacterial species.

Mycobacterium kansasii

Epidemiology

Mycobacterium kansasii is second to MAC as the cause of NTM lung disease. Tap water seems to be the most significant reservoir. The natural source of human infection is unclear but is likely by aerosol. As with other NTM, infections are not normally considered contagious from person to person.

Clinical infections

The most common manifestation is chronic pulmonary disease, closely resembling TB, involving the upper lobes, usually with evidence of cavitation and scarring. Most patients with pulmonary disease have underlying conditions including chronic obstructive pulmonary disease, bronchiectasis, pneumoconiosis, alcohol abuse, malignancies, and HIV infection. Extrapulmonary infections, such as lymphadenitis, skin and soft tissue infections, and joint infection, have been reported occasionally. Disseminated *M. kansasii* infection rarely occurs in immunocompetent individuals but has been reported in severely immunocompromised patients, particularly those with AIDS. In fact, infections are more common in HIV-infected individuals compared with those who are HIV negative.

Laboratory diagnosis

M. kansasii is a slowly growing organism that appears as long rods with distinct cross-banding. *M. kansasii* has an optimal growth temperature of 37° C, and colonies appear smooth to rough, with characteristic wavy edges and dark centers when grown on Middlebrook 7H10 agar. Some cording can usually be seen with low-power magnification. Colonies are **photochromogenic** (Fig. 26.2); that is, they form a pigment when exposed to light but are nonpigmented in the dark. With prolonged exposure to light, most strains form dark red crystals of β -carotene on the surface of and inside the colony, producing reddish-orange colonies. **Scotochromogenic** (produce pigment in light and dark) and **nonchromogenic** strains are rarely isolated. Most strains are strongly catalase positive (>45 mm in a semi-quantitative test); strains that are low catalase producers (<45 mm) are less commonly isolated.

Fig. 26.2 *Mycobacterium kansasii* growing on Löwenstein-Jensen medium showing photoreactivity. *Left*, Before exposure to light. *Right*, After exposure to light.

Characteristics that distinguish this species are a growth rate resembling that of *M. tuberculosis* at 35° C, strong photochromogenic properties, ability to hydrolyze Tween 80 in 3 days, strong nitrate reduction, and catalase production. A nucleic acid probe for the identification of *M. kansasii* isolates is commercially available. Molecular analysis has identified five subtypes; the one most commonly found in humans is subtype 1.

Mycobacterium genavense

Mycobacterium genavense has been reported as a cause of disseminated infections in patients with AIDS. It has also been associated with enteritis and genital and soft tissue infections in HIV-positive and HIV-negative immunocompromised patients. These slow-growing, fastidious mycobacteria have been recovered in BACTEC culture systems but failed to grow on subculture to routine solid media. Growth was obtained when Middlebrook 7H11 agar was supplemented with mycobactin. Isolates yield positive test results for semi-quantitative and heat-stable catalase, pyrazinamidase, and urease.

Mycobacterium haemophilum

The rare infections associated with *Mycobacterium haemophilum* occur primarily in patients who are immunocompromised. Approximately one half of the reported cases have occurred in patients with AIDS. Infections typically present as skin nodules on the extremities. Submandibular lymphadenitis, subcutaneous nodules, painful swellings, ulcers progressing to abscesses, and draining fistulas are often seen. *M. haemophilum* also causes cervical lymphadenopathy in otherwise healthy children.

A unique characteristic of this organism is its requirement for hemoglobin or hemin for growth. Isolation of this species is accomplished on media supplying the needed growth supplement, such as chocolate (CHOC) agar, Mueller-Hinton agar with 5% Fildes enrichment, and LJ medium containing 2% ferrous ammonium citrate. Successful isolation on Middlebrook 7H10 agar with an X factor disk planted in the inoculated

Fig. 26.3 *Mycobacterium marinum* on Middlebrook 7H10 medium producing rough colonies (×20).

area has been reported. Optimal growth temperature is 28° to 32° C; little or no growth occurs at 37° C. Colonies are rough to smooth and nonpigmented. Microscopically, the cells are strongly acid-fast, short, occasionally curved bacilli without banding or beading, and arranged in tight clusters or cords.

Mycobacterium marinum

Mycobacterium marinum has been implicated in diseases of fishes and is isolated from fishes in aquariums. Cutaneous infections in humans occur when salt water, or inadequately chlorinated freshwater containing the organism contacts traumatized skin. Outbreaks of cutaneous lesions in lifeguards have been reported. The typical presentation is a tender red or blue-red subcutaneous nodule, or “swimming pool granuloma,” usually occurring on the elbow, knee, toe, or finger 2 to 3 weeks after exposure. In some cases, an ulcer develops at the primary site of inoculation, with secondary spread along the ascending lymphatics. Treatment modalities include simple observation of minor lesions, surgical excision, anti-TB drug therapy, and the use of single antimicrobial agents. In vitro susceptibility testing shows that *M. marinum* is susceptible to rifampin and ethambutol, resistant to isoniazid and PZA, and partially resistant or intermediate to streptomycin.

M. marinum cells are moderately long to long rods with cross-barring. Colonies of this slowly growing organism are smooth to rough (Fig. 26.3) and wrinkled on inspissated egg medium but may be smooth when grown on Middlebrook 7H10 or 7H11 agar. *M. marinum* is photochromogenic; young colonies grown in the dark may be nonpigmented or buff, whereas colonies exposed to light develop a deep yellow color. Growth is optimal at incubation temperatures of 28° to 30° C. Preferences for growth at lower incubation temperatures, along with photochromogenicity, are clues to the identification of *M. marinum*. Some strains of *M. marinum* produce niacin; however, none reduce nitrate or produce heat-stable catalase. The organisms hydrolyze Tween 80 and produce urease and pyrazinamidase.

Mycobacterium scrofulaceum

Although rare in the United States, this bacterium can cause pulmonary tract infections in adults, and before being replaced by the MAC, *M. scrofulaceum* was the most common cause of cervical lymphadenitis in children. The infection manifests itself in one or more enlarged nodes, often adjacent

Fig. 26.4 *Mycobacterium scrofulaceum* on Löwenstein-Jensen medium.

to the mandible and high in the neck, with little or no pain. Patients are usually treated by surgical incision and drainage; anti-TB drugs are generally not necessary. Pulmonary infections caused by *M. scrofulaceum* typically appear with chronic structural lung disease or an immunomodulatory condition. *M. scrofulaceum* is often resistant to isoniazid, streptomycin, ethambutol, and *p*-aminosalicylic acid.

M. scrofulaceum is a uniformly staining, acid-fast, medium to long rod. The organism grows slowly (4 to 6 weeks) at incubation temperatures ranging from 25° to 37° C. Colonies are smooth with dense centers and pigmentation from light yellow to deep orange. The organism is scotochromogenic (Fig. 26.4). Members of this species do not hydrolyze Tween 80 or reduce nitrate but do produce urease and are high (>45 mm) catalase producers. These characteristics aid in differentiating this organism from other slowly growing scotochromogens, including certain strains of MAC, *M. gordonae*, and *M. szulgai*.

Mycobacterium simiae

The original strains of *Mycobacterium simiae* were isolated from the lymph nodes of monkeys. Although the organism has been recovered from tap water, there seems to be significant geographic variation in the incidence. For example, *M. simiae* is rarely isolated in most parts of the United States, but in parts of Texas, it is a relatively common isolate. Infrequent cases of human infection from *M. simiae* have been reported and are often associated with HIV-positive patients. Infection typically manifests as pulmonary disease, but lymphadenitis, skin lesions, and other presentations have been reported. Many isolates are resistant to most anti-TB drugs and are associated with significant morbidity and mortality.

Cells of *M. simiae* appear as short coccobacilli. When they are grown on inspissated egg medium at 37° C, smooth colonies appear in 10 to 21 days. Colonies on Middlebrook 7H10

agar are thin, transparent, tiny, and filamentous. The species is usually photochromogenic. Development of the yellow pigment may require prolonged incubation, whereas some strains may fail to produce pigment on exposure to light. Differential biochemical characteristics are the accumulation of niacin, negative nitrate reduction, and high-level, heat-stable catalase. *M. simiae* is one of the very few NTM that produce niacin, making it possible to confuse the identification with *M. tuberculosis* if pigment production under light is not observed.

Mycobacterium szulgai

A rare clinical isolate, the most common manifestation of *Mycobacterium szulgai* is pulmonary disease resembling TB. Extrapulmonary infections, including tenosynovitis of the hand, bursitis, osteomyelitis, keratitis, cervical lymphadenitis, and renal or cutaneous infection, have also been reported. This organism has been isolated from environmental sources such as snails, tropical fish, aquarium water, swimming pools, and hospital water supplies. Person-to-person transmission has not been documented. It is susceptible in vitro to most anti-TB drugs, and combination treatment is generally successful.

M. szulgai cells are medium to long rods, with some cross-barring. When cultured on egg-based medium at 37° C, the organism produces smooth and rough colonies. At 37° C, yellow-to-orange pigment develops in the absence of light and intensifies with exposure to light. Colonies grown at 22° C are nonpigmented or buff in the absence of light and develop yellow-to-orange pigment with light exposure. Characteristics that differentiate *M. szulgai* from other slowly growing mycobacteria are slow hydrolysis of Tween 80, positive nitrate reduction, and inability to grow in the presence of 5% sodium chloride.

Mycobacterium ulcerans

Mycobacterium ulcerans is a rare cause of mycobacteriosis in the United States but may be underreported because of difficulty in isolation. Worldwide, *M. ulcerans* is the third most common *Mycobacterium* spp., behind *M. tuberculosis* complex and *M. leprae*. The disease manifests as a painless nodule under the skin following trauma. A shallow ulcer, also referred to as a *Buruli ulcer*, develops that can be quite severe. Widespread ulcerative necrosis, osteomyelitis, and disfigurement can result. Patients rarely develop fever or systemic symptoms.

M. ulcerans cells are moderately long, without beading or cross-banding. These bacteria are fastidious and difficult to grow in vitro. Optimal growth temperature is 28° to 30° C, with little growth at 25° C and usually none at 37° C. The organism grows slowly, often requiring 6 to 12 weeks of incubation before colonies are evident. Colonies are smooth or rough and nonpigmented or lightly buff, and they do not develop pigment with exposure to light. *M. ulcerans* produces a heat-stable catalase but is inert in most other conventional biochemical tests. Molecular techniques are available that may improve detection.

Mycobacterium xenopi

Mycobacterium xenopi has been recovered from hot- and cold-water taps (including water storage tanks of hospitals)

and birds. The organism was first isolated from an African toad (*Xenopus laevis*) and was considered nonpathogenic for humans until 1965. Isolation of *M. xenopi* is relatively uncommon in the United States. Human cases of *M. xenopi* infection are mostly slowly progressive pulmonary infections in individuals with a predisposing condition, such as chronic obstructive pulmonary disease. The pulmonary infections present a clinical picture resembling that seen in patients with *M. tuberculosis*, *M. kansasii*, or MAC infection. Disseminated and extrapulmonary infections have also been reported, primarily in patients who are immunocompromised. Strains of *M. xenopi* are susceptible to the quinolones (ciprofloxacin, ofloxacin); some isolates are susceptible to vancomycin, erythromycin, or cefuroxime. In vitro susceptibility to anti-TB drugs is variable, with resistance only to ethambutol being the most common pattern.

M. xenopi cells are long filamentous rods. Colonies of this slowly growing mycobacterium on Middlebrook 7H10 agar are small, with dense centers and filamentous edges. Microscopic magnification observation of colonies growing on cornmeal-glycerol agar reveals distinctive round colonies with branching and filamentous extensions; aerial hyphae-like elements are usually seen in rough colonies. Furthermore, young colonies grown on cornmeal agar have a "bird's nest" appearance, with characteristic sticklike projections. Optimal growth temperature is 45° C; the organism grows more rapidly at this temperature than at 37° C and fails to grow at 25° C. *M. xenopi* has been classified with the nonphotochromogenic group; however, colonies are frequently bright yellow on primary isolation when incubated in the absence of light and when exposed to light. Distinctive characteristics, in addition to optimal growth at 42° C and yellow scotochromogenic pigment, are negative reactions for niacin accumulation, nitrate reduction, and positive reactions for heat-stable catalase, arylsulfatase, and pyrazinamidase.

Rapidly growing species

The three most important rapidly growing mycobacteria causing human infections are *Mycobacterium abscessus* subsp. *abscessus* (formerly *M. abscessus*), *Mycobacterium chelonae*, and the *Mycobacterium fortuitum* group. The *M. chelonae*/*M. abscessus* complex makes up one group within the rapidly growing mycobacteria. Posttraumatic wound infections are the most common infection associated with the rapidly growing mycobacteria. The *M. fortuitum* group causes about 60% of localized cutaneous infections.

Mycobacterium chelonae/*Mycobacterium abscessus* group

M. chelonae is found in the environment and is associated with many of the same opportunistic infections as those associated with the *M. fortuitum* group. *M. chelonae* is related closely to *M. abscessus* subsp. *abscessus* and is a commonly isolated rapidly growing *Mycobacterium*. It has caused sporadic cases of localized wound infections following medical or surgical procedures, including needle injections. The *M. chelonae*/*M. abscessus* complex is the most likely among the rapidly growing mycobacteria to be isolated from disseminated cutaneous infections in immunocompromised patients. *M. chelonae* has been associated with a variety of

infections of the skin, lungs, bone, central nervous system, and prosthetic heart valves. Approximately 80% of the cases of pulmonary disease resulting from rapidly growing mycobacteria are caused by *M. abscessus*. Infections by this organism have also been seen in patients with cystic fibrosis. Unlike with *M. chelonae*, tap water is an important reservoir for *M. abscessus*.

Microscopically, young cultures of *M. chelonae* are strongly acid fast, with pleomorphism ranging from long and tapered to short and thick rods. This rapidly growing *Mycobacterium* produces rough or smooth, nonpigmented to buff colonies within 3 to 5 days of incubation at 28° to 30° C. A positive 3-day arylsulfatase test result, nitrate reduction negative, and growth on MacConkey agar without crystal violet are characteristics that help differentiate *M. chelonae* and *M. abscessus* from other nonchromogenic, rapidly growing mycobacteria.

Mycobacterium fortuitum group

The *M. fortuitum* group contains 10 species. Common in the environment, *M. fortuitum* has been isolated from water, soil, and dust. The *M. fortuitum* group is the most common rapidly growing *Mycobacterium* associated with localized cutaneous infections, bone and joint infections, and abscesses at the site of puncture wounds. Infections associated with long-term use of intravenous and peritoneal catheters, injection sites, and surgical wounds following mammoplasty and cardiac bypass procedures have also been reported. Differences in susceptibility to antimicrobial agents occur among the rapidly growing species; thus in vitro susceptibility testing is often recommended for clinically significant isolates.

After 3 to 5 days of incubation at 35° C, *M. fortuitum* colonies appear rough or smooth and nonpigmented, creamy white, or buff. Microscopic examination of growth on cornmeal-glycerol and Middlebrook 7H11 agars after 1 to 2 days of incubation reveals colonies with branching filamentous extensions and rough colonies with short aerial elements. Cells are pleomorphic, ranging from long and tapered to short and thick rods. From most cultures, especially older ones, cells tend to decolorize and appear partially acid fast with any of the acid-fast staining techniques. Additional characteristics that distinguish *M. fortuitum* from other rapidly growing mycobacteria are the positive 3-day arylsulfatase test result and reduction of nitrate.

Mycobacterium smegmatis group

The *Mycobacterium smegmatis* group contains two species: *M. smegmatis* and *Mycobacterium goodii*. Commonly considered saprophytic, *M. smegmatis* has been implicated in rare cases of pulmonary, skin, soft tissue, and bone infections. It has been reported to cause granulomas in the soft tissue of the web space of a previously healthy 67-year-old patient who had no recollection of trauma to the hand.

Upon acid-fast staining, cells appear long and tapered or as short rods with irregular acid fastness. Occasionally, rods are curved with branching or Y-shaped forms; swollen, with deeper staining, beaded, or ovoid forms are sometimes seen. Colonies appearing on egg medium after 2 to 4 days are usually rough, wrinkled, or coarsely folded; smooth, glistening,

butyrous colonies may also be seen. Colonies on Middlebrook 7H10 agar are heaped and smooth or rough with dense centers. Pigmentation is rare or late; colonies appear nonpigmented, creamy white, or buff-to-pink in older cultures. In addition to the rapid growth rate and nonpigmented rough colonies, characteristics valuable in the identification of this organism are its negative arylsulfatase reaction, positive iron uptake, ability to reduce nitrate, and growth in the presence of 5% sodium chloride (NaCl) and on MacConkey agar without crystal violet.

Mycobacterium leprae

Mycobacterium leprae is the causative agent of Hansen disease (leprosy), an infection of skin, mucous membranes, and peripheral nerves. The disease is rare in the United States and other Western countries, yet it remains a major problem in other parts of the world. At one time, the WHO estimated that 11 million people had Hansen disease. However, the WHO launched an eradication program, and since 1985 the incidence of Hansen disease has been reduced by about 90%. Since 1995, the WHO has provided treatment free of charge to all patients with Hansen disease. Globally, the annual incidence has steadily declined since 2001 to 127,558 new leprosy cases detected in 2020. Currently, India, Brazil, and Indonesia account for about 80% of all new cases; each reported over 10,000 cases. In the United States, roughly 100 cases are reported annually, which are often acquired abroad.

Despite its reputation, Hansen disease is not highly contagious. The most important mode of transmission is not known, but the disease can be transmitted by direct contact and inhalation of aerosols from skin lesions. Shedding from the nasal passage is another route of transmission. The bacteria multiply slowly, producing a lengthy incubation period up to 20 years. The two extreme forms of the disease are tuberculoid leprosy, also called *paucibacillary Hansen disease*, and lepromatous leprosy, also called *multibacillary Hansen disease*. Symptoms of tuberculoid leprosy include hypopigmented or hyperpigmented skin macules and nerve involvement that can produce areas with loss of sensation (anesthesia). Patients eventually exhibit an effective CMI response. The optimal growth temperature for *M. leprae* is approximately 30° C, and because the patient mounts an adequate CMI response, the bacteria tend to remain in the extremities. Spontaneous recovery often occurs with tuberculoid leprosy.

Conversely, patients with lepromatous leprosy have a strong humoral-mediated immune response but not an effective CMI response. The disease is slowly progressive, and if untreated, it can be life-threatening. It is characterized by disfiguring skin lesions and progressive, symmetric nerve damage. Lesions of the mucous membranes of the nose can lead to destruction of the cartilaginous septum, resulting in nasal and facial deformities. The current recommended therapy for lepromatous leprosy consists of a combination of diaminodiphenylsulfone (dapsone) and rifampin for a minimum of 6 months. For tuberculoid leprosy, clofazimine is added, and treatment should be continued for 12 months.

The third and most common form is known as *borderline* or *dimorphous Hansen disease*. It presents as intermediate in severity. Skin lesions resemble those found in the tuberculoid form,

Fig. 26.5 *Mycobacterium leprae* from a skin biopsy in a patient with lepromatous leprosy (acid-fast smear stained with Ziehl-Neelsen stain, $\times 1000$).

but they are more numerous and can be found anywhere on the body. Peripheral nerves are affected, resulting in anesthesia and weakness. The lepromin skin test utilizes a standardized suspension of inactivated *M. leprae*. Like the PPD test for TB, a small volume is injected just under the skin and examined at 48 hours. Although it is not recommended for primary diagnosis, it can help differentiate between tuberculoid and lepromatous leprosy. Uninfected patients and those with lepromatous leprosy will be nonreactive, indicating a weak or negative CMI response. Individuals who were previously exposed and have a CMI response will have a reactive response, suggesting tuberculoid leprosy.

Laboratory diagnosis of Hansen disease depends on the microscopic demonstration of AFB from skin biopsy specimens. *M. leprae* has not been grown on artificial media. In patients with tuberculoid leprosy, organisms are extremely rare and may not be detected in skin scrapings or biopsy specimens. However, AFB are usually abundant in samples from patients with lepromatous leprosy (Fig. 26.5). *M. leprae* is not as acid fast or alcohol fast as in the case of other mycobacteria; as such, a weaker decolorizer consisting of 10% sulfuric acid is recommended instead of the standard acid-ethanol decolorizer. The bacteria are rod shaped, usually 1 to 7 μm long and 0.3 to 0.5 μm wide. The entire smear should be examined under oil immersion field ($\times 1000$) for the presence of the microorganisms. PCR assays are also available to definitively detect the bacteria.

Isolation and identification of mycobacteria

Growth rate, colony morphology, pigmentation, nutritional requirements, optimal incubation temperature, and biochemical test results are traditional criteria used to differentiate species within the genus *Mycobacterium* (Table 26.1). Rapid techniques include broth-based culture systems, including some that monitor cultures continuously during the incubation period. However, because phenotypic identification of the slowly growing mycobacteria is not sufficient for accurate species identification, molecular-based assays are the reference method. A limited number of species-specific nucleic acid probes offer rapid identification of culture isolates.

Data on *M. fallax* from Levy-Frebault, V., et al. (1983). *Mycobacterium fallax* sp. nov. *International Journal of Systematic and Evolutionary Microbiology*, 33, 336.

N, Nonphotochromogenic; P, photochromogenic; S, scotochromogenic; TB, tuberculosis; T2H, thiophene-2-carboxylic acid hydrazide; V, variable.w

Researchers have developed PCR assays that have increased the sensitivity of nucleic acid probes. Other techniques, such as high-pressure liquid chromatography (HPLC) and MALDI-TOF mass spectrometry, have been used recently to distinguish mycobacterial species and have become routine in many laboratories.

Laboratory safety considerations

The serious nature of TB and the usual airborne route of infection require that special safety precautions be used by anyone handling mycobacterial specimens. The incidence of TB (i.e., skin test positivity) in those who work in the mycobacteriology laboratory is at least three times higher than that among other laboratory personnel in a given institution. However, the hazard of working in a mycobacteriology laboratory is minimal if the laboratory is well designed, has appropriate equipment, and precautions are followed closely.

Personnel safety

The administration of the microbiology laboratory must ensure that each employee is (1) provided with adequate safety equipment, (2) trained in safe laboratory procedures, (3) informed of the hazards associated with the procedures, (4) prepared for action following an accident, and (5) monitored regularly by medical personnel. Laboratory personnel must use appropriate safety equipment and follow established protocols. A skin test (Mantoux) with PPD should be administered on the first day of employment and thereafter regularly to persons previously skin test negative. Individuals known to be previously skin test positive should be counseled regularly and referred for medical evaluation if their health status changes.

Personal protective equipment (PPE) provides safety for staff working in the mycobacteriology laboratory. All manipulations with cultures or specimens should be done with gloves and laboratory coats or gowns. In addition, respirators must be used when performing procedures outside the biological safety cabinet when aerosolization could result. The minimum level of respiratory protection is a respirator that contains a National Institute for Occupational Safety and Health–certified N series filter with a 95% efficiency rating (N-95). In addition to being trained to use the respirator, laboratory staff must be fit-tested.

Ventilation

Laboratory design and ventilation play important roles in mycobacteriology laboratory safety. Ideally, the mycobacteriology laboratory should be separate from the remainder of the laboratory and have a nonrecirculating ventilation system. The area in which specimens and cultures are processed should have negative air pressure in relation to other areas; that is, the air flow should be from clean areas (e.g., corridors) into less clean areas (e.g., the mycobacteriology laboratory). There must be 6 to 12 room air changes per hour to effectively remove 99% or more of airborne particles within 30 to 45 minutes. A much higher number of room air changes per hour can cause problems of air turbulence within the biological safety cabinets.

Biological safety cabinet

Because the route of infection by mycobacteria is primarily through inhalation, it is essential that the dispersal of organisms into the air be minimized and that inhalation of airborne bacilli be avoided. The biological safety cabinet is the single most important piece of equipment in a mycobacteriology laboratory. Various types of safety cabinets are available, including class I negative-pressure cabinets and class II vertical, laminar flow cabinets (see [Chapter 4](#)). Proper installation, maintenance, and testing are essential to their performance. Each safety cabinet should be tested and recertified at least yearly by trained personnel with special monitoring equipment. Processing clinical specimens or transferring viable cultures outside a safety cabinet should not be permitted.

To prevent the dispersal of infectious aerosols into the laboratory area, all potentially infectious materials should be tightly covered when they are outside the biological safety cabinet. Specimens should be centrifuged in aerosol-free safety carriers, and the tubes should be removed from the safety carriers only inside the biological safety cabinet. Specimens taken out of the safety cabinet for transport to a decontamination area must be covered. After the safety cabinet work area has been cleaned with disinfectant, the ultraviolet (UV) light, which kills microorganisms, inside the cabinet should be used to eliminate any further contamination of surfaces and airborne bacteria. Because of the hazards to skin and eyes associated with excess UV light, the UV light should be turned on only when the safety cabinet is not in use.

For sterilizing a wire-inoculating loop, an electric incinerator should be used within the biological safety cabinet. Single-use, disposable sterile applicator sticks or plastic transfer loops are also recommended. Splashproof discard containers must be used to prevent aerosol formation and possible cross-contamination of samples.

Use of proper disinfectant

Covering the work surface with a towel or absorbent pad soaked in a disinfectant reduces the accidental creation of infectious aerosols. In the selection of a disinfectant for the mycobacteriology laboratory, the product brochure should be consulted to ensure that the disinfectant is bactericidal for mycobacteria (tuberculocidal). Sodium hypochlorite is effective at a concentration of 0.05% to 0.5% (e.g., a 1:50 to 1:10 dilution of most household bleaches). The solution should be made fresh daily, and contact time should be 10 to 30 minutes. Sodium hypochlorite loses effectiveness in the presence of a large amount of protein material. Phenol-soap mixtures containing ortho-phenylphenol, such as Amphyl (Reckitt Benckiser North America, Wayne, NJ), or other phenolic derivatives are effective with contact periods of 10 to 30 minutes. Solutions of 5% phenol are no longer recommended because of toxicity to humans.

Specimen collection

Mycobacteria can be recovered from a variety of clinical specimens, primarily those from the lower respiratory area but also urine, feces, blood, CSF, tissue biopsy material, and aspirates of any tissue or organ. Thus successful isolation of mycobacteria from clinical specimens begins with properly collected and handled specimens. Whenever possible,

diagnostic specimens should be collected before the initiation of therapy. All specimens should be transported to the laboratory immediately after collection. If immediate transport is not possible, the specimen may be refrigerated overnight. Ideally, laboratories should process specimens for mycobacteria daily because delays in processing may lead to false-negative cultures and increased bacterial contamination.

Each specimen should be confined to a single collection in an individual collection container recommended by the laboratory providing the requested diagnostic service. The most recommended container is a sterile, wide-mouthed cup with a tightly fitted lid. Special sterile receptacles containing a 50-mL centrifuge tube for sputum collection are also available commercially. Because of small sample volumes, the use of swabs for clinical specimens is discouraged. As with all specimens for microbiological examination, aseptic collection is important.

The spectrum of illness caused by *Mycobacterium* spp. is so broad that almost any site can yield an acceptable specimen. Each specimen type, even when properly collected, transported, and processed, may have an intrinsic maximal yield. This can be the result of tubercle burden at the collection site or of environmental effects, such as pH, that can affect recovery. Emphasis should be placed on collecting the number and types of specimens that when transported and processed correctly maximize the diagnostic yield. Box 26.2 lists the types of clinical samples acceptable for mycobacteriologic culture.

Sputum and other respiratory secretions

Although a variety of clinical specimens may be submitted to the laboratory to recover *M. tuberculosis* and NTM, respiratory secretions, such as sputum and bronchial aspirates,

are the most common. An early-morning specimen should be collected on 3 consecutive days, although studies have suggested that the addition of a third specimen does not significantly increase the sensitivity of detecting mycobacteria. Pooled specimens are unacceptable because of increased contamination with oral microbiota. The number of specimens necessary to obtain culture confirmation and perform susceptibility testing is related to the frequency of smear positivity. If at least two of the first three sputum direct smears are positive, then three specimens are often sufficient to confirm a diagnosis. However, when none or only one of the first three sputum smears is positive, additional specimens are needed for culture confirmation. Smear positivity and culture yield differ with the extent of the disease (i.e., whether there is cavitary or noncavitary pulmonary disease or endobronchial or laryngeal disease).

A volume of 5 to 10 mL of sputum produced by deep coughing and expectoration of sputum or induced by inhalation of an aerosol of hypertonic saline should be used. Induced sputum specimens increase the chances of detection and yield of mycobacteria. When sputum is not obtainable, bronchoscopy may be performed to obtain samples, such as bronchial washing, bronchoalveolar lavage (BAL), or transbronchial biopsy specimen. Brushings appear to be more commonly diagnostic compared with washing or biopsy specimens, possibly because of an inhibitory effect on the mycobacteria caused by the lidocaine used during bronchoscopy or because of dilution of the specimen with saline. Often patients can produce sputum for several days after bronchoscopy; these samples should be collected and examined.

Gastric aspirates and washings

Gastric aspirates are used to recover mycobacteria that may have been swallowed during the night. Use of this type of specimen should be only for patients who do not produce sputum by aerosol induction, for children younger than 12 years of age, and for nonambulatory individuals. Because children have difficulty producing sputum, gastric aspiration is recommended. Gastric lavage has been reported to be better than BAL for the detection of mycobacteria in children. When BAL was compared with three morning gastric lavage specimens, diagnosis of childhood pulmonary TB could be made in 10% with BAL versus 50% with morning gastric lavage. This has not appeared to be the case in adults. Gastric lavage may offer a diagnostic alternative only for those unable to expectorate sputum and in whom BAL might be contraindicated. Gastric aspirates should be obtained in the morning after overnight fasting. Three specimens should be collected within 3 days. Sterile water, 30 to 60 mL, is instilled orally or via nasogastric tube aspiration. Prolonged exposure to gastric acid kills mycobacteria and diminishes culture yield. Specimen processing should be done expeditiously, or the specimen should be neutralized with sodium carbonate or another buffer to pH 7.0 as soon as possible after specimen collection.

Urine

For examination of urine, first-morning midstream specimens collected on 3 successive days are preferred. The entire volume of voided urine, or a minimum of 15 mL, is collected

BOX 26.2 Acceptable specimens for mycobacterologic culture

Respiratory specimens

- Spontaneously expectorated sputum
- Normal saline-nebulized, induced sputum
- Transtracheal aspirate
- Bronchoalveolar lavage
- Bronchoalveolar brushing
- Laryngeal swab
- Nasopharyngeal swab

Body fluids

- Pleural fluid
- Pericardial fluid
- Joint aspirate
- Gastric aspirate
- Peritoneal fluid
- Cerebrospinal fluid
- Stool
- Urine
- Pus

Body tissues

- Blood
- Bone marrow biopsy/aspirate
- Solid organ
- Lymph node
- Bone
- Skin

in a sterile container. A specimen may be collected through an indwelling catheter with a sterile needle and syringe. Urine specimens should be refrigerated during the interval between collection and processing; specimens should be processed promptly. As a rule, pooled specimens collected over 12 to 24 hours are not recommended. Such specimens are more subject to contamination and may contain fewer viable tubercle bacilli.

Stool

Examination of stool specimens for the presence of AFB can be useful in identifying patients, such as those with AIDS, who may be at risk for developing disseminated mycobacterial disease resulting from MAC. Frequently, the number of organisms found in the bowel in these patients is quite high, although it has been reported that 68% of MAC culture-positive stool specimens are acid-fast-smear negative. Stool specimens should be collected in clean containers without any preservative and sent directly to the laboratory for processing. If processing within a few hours is not possible, the specimen should be frozen at -20°C until it is processed. Culture of feces for mycobacteria from patients other than those with or at risk for AIDS is usually not warranted.

Blood

Mycobacteremia, once considered rare, is now often seen in patients with AIDS but is seen less frequently in other immunocompromised hosts. Most infections are caused by MAC. Recovery of the organism from blood is associated with clinical disease. The Isolator lysis-centrifugation system (Wampole Laboratories, Cranbury, NJ) has been reliable and recommended for blood samples for many years. Alternative recovery systems include direct inoculation of blood into a MYCO/F bottle (BD Diagnostic Systems) or the BacT/Alert MB blood medium (bioMérieux, Durham, NC). The collection systems are considered equivalent, although the Isolator system allows quantitative analysis, which may be used to monitor therapy and evaluate prognosis.

Tissue and other body fluids

At times, tissue and other body fluids might be needed for microscopic examination and culture. Whenever possible, CSF specimens should be from large-volume lumbar punctures to increase diagnostic yield. Diagnosis of tuberculous meningitis is extremely difficult. Peritoneal (ascitic fluid) smears are also rarely positive for AFB. Culture of large volumes and inoculation of the specimen into mycobacterial liquid media can help maximize yield in dilute specimens.

When noninvasive techniques have failed to provide a diagnosis, surgical procedures may be considered. Specimens obtained from the lung, pericardium, lymph nodes, bones, joints, bowel, or liver may be appropriate. The tissue or fluid should be collected aseptically and placed in a sterile container. If the tissue is not processed immediately, a small amount (10 to 15 mL) of sterile saline should be added to prevent dehydration. It may be necessary to collect fluid containing fibrinogen (e.g., pleural, pericardial, peritoneal) in a container with an anticoagulant. The amount of liquid recommended for culture differs—2 mL for CSF, 3 to 5 mL

for exudates and pericardial and synovial fluids, and 10 to 15 mL for abdominal and chest fluids. Immediate processing of these samples is important. When tissue is collected, histologic evaluation may reveal caseating or noncaseating granuloma formation with the presence of multinucleated giant cells. These histologic changes are consistent with but not specific for mycobacterial disease.

Digestion and decontamination of specimens

To ensure optimal recovery of mycobacteria from clinical specimens, many specimens must be processed before inoculation onto culture media. Each step must be conducted with precision. Specimens from sterile body sites can simply be concentrated by centrifugation (if a large volume) and inoculated. However, specimens that may contain commensal bacteria should be decontaminated and then concentrated.

Many clinical specimens, such as sputum specimens, contain mucin or organic debris that surrounds the bacteria in the sample. An abundance of nonmycobacterial organisms, and possible mycobacteria, make up the microbiota of these specimens. When placed onto culture media, the abundant nonmycobacterial organisms can quickly overgrow the more slowly growing mycobacteria. The purposes of the digestion-decontamination process are to (1) liquefy the sample by digesting the proteinaceous material and (2) allow the chemical decontaminating agent to contact and kill the nonmycobacterial organisms. The high lipid content in the cell wall of mycobacteria makes them somewhat less susceptible to the killing action of various chemicals. After liquefaction of the specimen, the surviving mycobacteria can be concentrated with centrifugation. Additionally, liquefying the mucin enables the mycobacteria to contact and use the nutrients of the medium onto which they are subsequently inoculated.

Specimens that contain mucus and require digestion and decontamination include sputum, gastric washing, BAL, bronchial washing, and transtracheal aspirate specimens. Voided urine, autopsy tissue, abdominal fluid, and any contaminated fluid require decontamination. Specimens from normally sterile sites, such as blood, CSF, synovial fluid, and biopsy tissue from deep organs, do not require decontamination. Sterility should be strictly maintained in collection and transport. Stool decontamination is especially difficult and may require repeated attempts.

Decontamination and digestion agents

Each laboratory should maintain a proper balance between the rate of recovery of mycobacteria and suppression of contaminating bacterial growth. Failure to isolate mycobacteria from patients with signs and symptoms of classic mycobacterial disease may indicate that the decontamination is too harsh. However, if more than 5% of all specimens cultured are contaminated, the decontamination procedure may be inadequate. In general, a range that is considered acceptable in this delicate balance is between 2% and 5% of bacterially contaminated mycobacterial cultures. The bactericidal action of a decontaminating agent is influenced by the concentration of the chemical agent, exposure time, and temperature; therefore alterations in any of these factors can affect the bactericidal effect. The optimal decontamination procedure requires

an agent that is mild and yields growth of mycobacteria while controlling contaminants. The use of selective media may diminish the need for harsh decontamination procedures.

Sodium hydroxide

Sodium hydroxide (NaOH), at a concentration of 2%, 3%, or 4%, serves as a digestant and decontaminating agent. It is a commonly used decontaminant but must be used with caution because it is only slightly less harmful to the mycobacteria than to the contaminating organisms.

N-acetyl-L-cysteine

A combination of a liquefying agent, such as N-acetyl-L-cysteine (NALC) or dithiothreitol, plus NaOH is commonly used. The liquefying agent has no inhibitory effect on bacterial cells; however, liquefaction of the sample allows the decontaminating chemical to come into uniform contact with the contaminating bacteria more readily. When contamination can be controlled with a lower concentration of NaOH, the recovery of mycobacteria is indirectly improved using the milder procedure because fewer mycobacteria are lost in the process. The addition of chlorhexidine has improved the recovery of NTM from sputum samples from patients with cystic fibrosis because of the inhibition of *Pseudomonas aeruginosa*, which is found in the respiratory tract of 80% of these patients. See [Appendix D](#) on Evolve for the NALC-NaOH digestion-decontamination procedure.

Benzalkonium chloride

Another digestant-decontamination procedure uses benzalkonium chloride (Zephiran) combined with trisodium phosphate (TSP). TSP rapidly liquefies sputum but requires a long exposure time to decontaminate the specimen. Benzalkonium chloride shortens the exposure time and effectively destroys many contaminants, with little bactericidal effect on tubercle bacilli. The addition of phosphate buffer to digested specimens results in greater isolation of mycobacteria. Benzalkonium chloride is bacteriostatic for tubercle bacilli, necessitating neutralization before plating or the use of egg-based media to exploit its inherent neutralizing capacity.

Oxalic acid

Oxalic acid, 5%, can also be used to decontaminate specimens contaminated with *P. aeruginosa*. This method is reported to be better than other alkali decontamination procedures when *P. aeruginosa* and certain other contaminants are present. Oxalic acid-treated specimens can be used with the broth-based culture systems.

Concentration procedures

The specific gravity of the tubercle bacilli ranges from 0.79 to 1.07. Because of the low specific gravity of the AFB, a low centrifugal force has a buoyant rather than a sedimenting effect. Excess mucus will compound this phenomenon. Treatment with mucolytic agents, such as NALC, splits mucoprotein, allowing greater sedimentation of AFB. Concentration centrifugation speeds must be at least 3000 times the gravitational constant (*g*) to maximize recovery.

Lower *g* necessitates longer centrifugation time. The consequences of longer centrifugation time are prolonged exposure to the toxic effects of the digestion-decontamination agents

used and the higher temperatures generated by unrefrigerated centrifuges. In summary, the digestion-decontamination agent used, its concentration, the length of exposure of the specimen to the agent, and the centrifugation speed and temperature all affect the recovery of *Mycobacterium* spp.

Staining for acid-fast bacilli

When Gram-stained, *Mycobacterium* spp. do not stain or stain faintly, giving a beaded appearance because of irregular uptake of the stain caused by the increased lipid content of the cell wall. Acid-fast smears are prepared directly from clinical specimens and from digested, decontaminated, and concentrated specimens.

The conventional acid-fast staining methods, Ziehl-Neelsen and Kinyoun, use carbolfuchsin as the primary stain, acid-alcohol as a decolorizing agent, and a methylene blue counterstain. The Ziehl-Neelsen staining procedure involves the application of heat with the carbolfuchsin stain, whereas the Kinyoun acid-fast stain is a cold stain. The Ziehl-Neelsen method tends to provide more consistent results. Because of the potential cross-contamination of AFB from one smear to another, careful attention should be paid to the staining technique. Staining jars should not be used. Smears should not contact one another when placed on staining racks. Slides are examined using a $\times 100$ oil immersion objective on a light microscope for 15 minutes, viewing a minimum of 300 fields before a slide is called *negative*.

The **auramine stain** or **auramine-rhodamine fluorochrome stain** is more sensitive than the carbolfuchsin stains. About 18% of all culture-positive specimens have smears that are positive on the auramine-rhodamine stain but negative on the Kinyoun or Ziehl-Neelsen stain. In addition, smears can be screened at a lower magnification ($\times 250$ to $\times 400$), thus allowing more fields to be examined in a shorter time. A fluorescence microscope equipped with an appropriate filter system is needed for the examination of a fluorochrome-stained smear. The smear is examined under a mercury vapor lamp with a strong, blue-filtered light. Positive smears reveal bright, yellow-orange bacilli against a dark background. Smears being examined for AFB should be carefully examined with a minimum of 300 fields, and three horizontal sweeps of a smear that is 2 cm long and 1 cm wide should be performed. Less than 10% of the rapidly growing mycobacteria may be acid fast; they may not stain at all with fluorochrome stains. If rapidly growing mycobacteria are suspected, smears should be stained with carbolfuchsin and a weaker decolorizing process used.

Individuals with extensive disease shed large numbers of organisms. However, many individuals have subtle infections from which fewer organisms will be shed. Thus the overall sensitivity of the acid-fast smear ranges from 20% to 80%, depending on the extent of the infection. Even with concentration techniques, the number of organisms observed on a smear will be considerably less than the number of organisms seen on a smear from an individual with bacterial pneumonia. The CDC has made recommendations regarding the interpretation and reporting of acid-fast smears ([Table 26.2](#)). In the interpretation of a smear as positive for AFB, laboratory scientists must realize that organisms other than *Mycobacterium* such as *Nocardia* spp., *Legionella micdadei*, and *Rhodococcus* spp. might stain at least partially acid fast.

Table 26.2 Acid-fast smear interpretation

Number of acid-fast bacilli seen		Quantitative report
Carbolfuchsin stain, ×1000	Fluorochrome stain, ×450	
0	0	No acid-fast bacilli seen
1–2/300 fields	1–2/70 fields	Doubtful acid-fast bacilli seen; resubmit another specimen for examination
1–9/100 fields	1–2/70 fields	1 +
1–9/10 fields	2–18/50 fields	2 +
1–9/field	4–36/field	3 +
>9/field	>36/field	4 +

Modified from Kent, P. T. & Kubica, G. P. (1985). *Public health mycobacteriology: a guide for the level III laboratory*. Atlanta, GA: Centers for Disease Control and Prevention.

Culture media and isolation methods

Mycobacteria are strictly aerobic and grow more slowly than most bacteria pathogenic for humans. The generation time of mycobacteria is longer than 12 hours; *M. tuberculosis* has the longest replication time, at 20 to 22 hours. The rapidly growing species generally form colonies in 2 to 3 days, whereas most pathogenic mycobacteria require 2 to 6 weeks of incubation. The growth of *M. tuberculosis* is enhanced by an atmosphere of 5% to 10% CO₂. Mycobacteria have an optimal pH between 6.5 and 6.8 and grow better in higher humidity. Most human pathogenic mycobacteria grow best at temperatures of 35° to 37° C. However, when mycobacteria are suspected in skin and soft tissue specimens, a second set of culture media should be incubated at 25° to 33° C for the recovery of *M. haemophilum*, *M. marinum*, *M. ulcerans*, and *M. chelonae*. One of the mycobacteria pathogenic for humans, *M. genavense*, does not grow on media used routinely to isolate mycobacteria and requires extended incubation (6 to 8 weeks), whereas *M. leprae* fails to grow on artificial media.

The many different media available for the recovery of mycobacteria from a clinical specimen are variations of three general types (Table 26.3): egg-based media, serum albumin agar media, and liquid media. Within each general type, there are nonselective formulations and formulations that have been made selective by the addition of antimicrobial agents. Because some isolates do not grow on a particular agar and each type of culture medium offers certain advantages, a combination of culture media is generally recommended for primary isolation. The use of a solid-based medium, such as LJ medium, in combination with a liquid-based medium is recommended for routine culturing of specimens for the recovery of AFB. Current guidelines recommend that two or more types of media be used when attempting to recover mycobacteria.

Egg-based media

The basic ingredients in an inspissated egg medium, such as LJ (the most used egg-based medium), Petragnani, and American Thoracic Society (ATS) media, are fresh whole eggs, potato flour, and glycerol, with slight variations in defined salts, milk, and potato flour. Each contains malachite green to suppress the growth of gram-positive bacteria. Selective media that contain antimicrobial agents, such as the Gruft

modification of LJ medium and Mycobactosel (BD Diagnostic Systems), are sometimes used in combination with nonselective media to increase the isolation of mycobacteria from contaminated specimens. The nonselective egg-based media have a long shelf life up to 1 year, but distinguishing early growth from debris is sometimes difficult.

Agar-based media

Agar-based media are better chemically defined than egg-based media, and they do not readily support the growth of contaminants. Serum albumin agar media, such as Middlebrook 7H10 and 7H11 agars, are prepared from a basal medium of defined salts, vitamins, cofactors, glycerol, malachite green, and agar combined with enrichment consisting of oleic acid, bovine albumin, glucose, and beef catalase (Middlebrook OADC enrichment). **Middlebrook 7H11 medium** also contains 0.1% casein hydrolysate, which improves the recovery of isoniazid-resistant strains of *M. tuberculosis*. The addition of antimicrobial agents to 7H10 or 7H11 medium makes the media more selective by suppressing the growth of contaminating bacteria. Mitchison selective 7H11 agar contains polymyxin B, amphotericin B, carbenicillin, and trimethoprim lactate.

In contrast with opaque egg-based media, clear agar-based media can be examined using a dissecting microscope for early detection of growth and colony morphology. Drug susceptibility tests may be performed on agar-based media without altering drug concentrations, as occurs with egg-based media. When specimens are inoculated onto Middlebrook 7H10 and 7H11 media and incubated in an atmosphere of 10% CO₂ and 90% air, 99% of the positive cultures are detected in 3 to 4 weeks, earlier than for those detected on egg-based media. Certain precautions should be followed in the preparation, storage, and incubation of Middlebrook media. Both excess heat and exposure of the prepared media to light can result in the release of formaldehyde, which is toxic to mycobacterial growth.

A CHOC agar plate should be included in the primary isolation media for skin and other body surface specimens for the recovery of *M. haemophilum*, which requires ferric ammonium citrate or hemin for growth. Alternatively, a Middlebrook 7H10 agar plate supplemented with hemolyzed sheep red blood cells or another source of hemin may be used. The plate should be incubated at 30° C, the optimal temperature for recovery of this organism.

Table 26.3 Mycobacterial culture media

Medium	Composition	Inhibitory agents
American Trudeau Society	Fresh whole eggs, potato flour, glycerol	Malachite green (0.02%)
Petragnani	Fresh whole eggs, egg yolks, whole milk, potato, potato flour, glycerol	Malachite green (0.12%)
Middlebrook 7H9	Defined salts, vitamins, cofactors base, with pyruvate, albumin, catalase, glucose,	
Middlebrook 7H10	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose	Malachite green (0.00025%)
Middlebrook 7H11	Middlebrook 7H10 medium with 0.1% casein hydrolysate	Malachite green (0.0001%) Amphotericin B Nalidixic acid Trimethoprim Azlocillin Amphotericin B Nalidixic acid Trimethoprim Azlocillin
Gruft (modification of LJ)	Fresh whole eggs, defined salts, glycerol, potato flour, RNA	Malachite green Penicillin Nalidixic acid
Mycobactosel (BBL, BD Diagnostic Systems, Sparks, MD) LJ	Fresh whole eggs, defined salts, glycerol, potato flour	Malachite green Cycloheximide Lincomycin Nalidixic acid
Middlebrook 7H10 (selective)	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose	Malachite green Cycloheximide Lincomycin Nalidixic acid
Mitchison's selective 7H11	Middlebrook 7H10 medium with casein hydrolysate	Carbenicillin Amphotericin B Polymyxin B Trimethoprim lactate

LJ, Löwenstein-Jensen; SPS, sodium polyanethol sulfonate.

Liquid media

Mycobacterium spp. grow more rapidly in liquid medium, and it can be used for both primary isolation and subculturing. Liquid culturing systems have been demonstrated to be superior in the recovery of mycobacteria from clinical specimens compared with conventional solid media. Middlebrook 7H9 broth and Dubos Tween albumin broth are nonselective liquid media used for subculturing stock strains, picking single colonies, and preparing inoculum for in vitro testing. Numerous automated systems that use liquid media are available.

The mycobacterial growth indicator tube (MGIT) system (BD Diagnostic Systems) uses modified Middlebrook 7H9 broth with a fluorescence quenching-based oxygen sensor for detecting mycobacterial growth. Oxygen present in the sterile medium quenches the fluorescence. Bacterial growth consumes the oxygen, allowing fluorescence when the tube is exposed to UV light. In the manual system, a Wood lamp or

transilluminator can be used. Before use, oleic acid–albumin–dextrose is added to stimulate growth of mycobacteria. To inhibit growth of nonmycobacteria, the antimicrobial agents polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin (PANTA) are added. The MGIT 960 system (BD Diagnostic Systems) is a continuous monitoring system.

Other continuous monitoring systems include the MB/BacT Alert 3D system (bioMérieux), which uses a colorimetric carbon dioxide sensor in each bottle to detect bacterial growth, and the VersaTREK culture system (VersaTREK Diagnostic Systems, Cleveland, OH). The VersaTREK culture system is based on the detection of pressure changes in the headspace above the broth medium in a sealed culture bottle resulting from gas production or consumption during microbial growth. Each manufacturer provides a mixture of antimicrobial agents to be added to each culture vial at the time of inoculation. The continuous monitoring systems have similar

performance and operational features. Bottles are incubated in the instrument for the entire monitoring period, and options for electronic data management are available. The MGIT 960 and VersaTREK systems have also been approved for antimicrobial susceptibility testing. A disadvantage of the liquid systems is that no colony morphology or pigmentation is available to suggest that the growth is of a mycobacterial species and not that of a contaminant or commensal organism. Another limitation is that cultures with mycobacteria with a lower optimal temperature, such as *M. haemophilum*, *M. marinum*, *M. ulcerans*, and *M. chelonae*, may not be detected.

Isolator lysis-centrifugation system

Isolator is a blood collection system that contains saponin to liberate intracellular organisms. After saponin treatment and centrifugation, the sample is inoculated onto mycobacteria agar plates or tubes. The system allows higher yields and shorter recovery times for mycobacteria than conventional blood culture methods. It offers the advantage of yielding isolated colonies and the ability to quantify mycobacteremia, which may be useful in monitoring the effectiveness of therapy in disseminated MAC infection.

For maximal recovery of mycobacteria, laboratories should use a battery of media that includes a liquid medium and at least one solid medium—egg-based or agar-based—for primary isolation. An additional selective medium is often reserved for specimens in which heavy contamination is anticipated.

Case check 26.2

In the patient presented in the Case in Point, no organisms were seen on the direct smears of all three samples submitted. Nucleic acid amplification tests are a rapid, more sensitive method to directly detect mycobacteria. Cultures are more sensitive than direct smears, as well, for diagnosing TB, and broth cultures are preferred. The BACTEC broth cultures were ultimately positive in this patient.

Laboratory identification

Laboratory levels or extents of service

A change in the distribution of mycobacterial laboratory testing led to the development of levels of service by the ATS and extents of service by the College of American Pathologists (CAP) to maintain quality of service. According to CAP, laboratories must decide which level of mycobacterial services to offer: level 1, specimen collection only; level 2, perform microscopy and isolate and identify and sometimes perform susceptibility tests for *M. tuberculosis*; or level 3, perform microscopy, isolate and identify, and perform susceptibility tests for all *Mycobacterium* spp. (Box 26.3). A facility's selection of a level of service depends on the volume of specimens submitted, patient populations served, ability to perform the requested tests according to comfort; biological safety level and staff training in performance of each requested test; and the time, effort, and funds allocated for the service. The procedures available in a mycobacteriology laboratory differ with the level of service of that laboratory.

BOX 26.3 Levels of service as defined by the American Thoracic Society and College of American Pathologists

Extent of service as defined by the American Thoracic Society

- Specimen collection only; no mycobacteriologic procedures performed; all specimens sent to another laboratory
- Acid-fast stain, inoculation, or both; identification by a reference laboratory
- Isolation and definitive identification of *Mycobacterium tuberculosis*; preliminary grouping of nontuberculous *Mycobacterium* spp., with definitive identification at a reference laboratory
- Definitive identification of all mycobacterial isolates with assistance in the selection of therapy, with or without drug susceptibility testing

College of American Pathologists levels of service

- Level 1: Specimen collection only; no mycobacteriologic procedures performed; all specimens are sent to another laboratory
- Level 2: Perform microscopy. Isolate, identify, and sometimes perform susceptibility tests for *M. tuberculosis*
- Level 3: Perform microscopy. Isolate, identify, and perform susceptibility tests for all species of *Mycobacterium*

Preliminary identification of mycobacteria

Once an isolate has been recovered in the mycobacteriology laboratory, certain characteristics can be used to classify the isolate before performing biochemical or molecular tests. The first step is to confirm that the isolate recovered in broth or on solid media is an acid-fast organism by performing acid-fast staining. Then, phenotypic characteristics, such as colony morphology, growth rate, optimal growth temperature, and photoreactivity, can help speciate the mycobacteria. These characteristics do not allow definitive identification but are presumptive and help in the selection of other, more definitive tests. Historically, the Runyon classification used the rate of growth and pigment production to place the NTM into one of four categories. However, because of variability within individual species for these two criteria, the Runyon classification is no longer used today. Figs. 26.6 and 26.7 show schematic diagrams for the identification of slowly growing and rapidly growing *Mycobacterium* spp., respectively. See Table 26.1 for a summary of the identification characteristics of clinically important mycobacteria.

Colony morphology

Colonies of mycobacteria are generally distinguished as having a smooth and soft or rough and friable appearance. Colonies of *M. tuberculosis* that are rough often exhibit a prominent patterned texture referred to as *cording* (curved strands of bacilli); this texture is the result of tight cohesion of the bacilli. Colonies of MAC have a variable appearance, with glossy whitish colonies often occurring with smaller translucent colonies.

Growth rate

Growth rate and recovery time depend on the species of mycobacteria but are also influenced by the media, incubation temperature, and initial inoculum size. The range in recovery time is wide, from 3 to 60 days. Mycobacteria are generally categorized as rapid growers, having visible growth in fewer than 7 days, or slow growers, producing colonies in more than

Fig. 26.6 Schematic diagram for the identification of slowly growing *Mycobacterium* spp. Exceptional reactions occur. Organisms should be subjected to a battery of morphologic and physiologic tests before final identification is made. LJ, Löwenstein-Jensen medium; SQ, semi-quantitative.

7 days. Determination of growth rate should be evaluated from the time of subculture, not from the time of detection from the clinical sample. The inoculum should be sufficiently small to produce isolated colonies. Microscopic examination of agar for microcolonies allows earlier detection of growth.

Temperature

The optimal temperature and range at which a mycobacterial species can grow may be extremely narrow, especially at the time of initial incubation. *M. haemophilum*, *M. marinum*, *M. ulcerans*, and *M. chelonae* grow best at 25° to 33° C and poorly, if at all, at 35° to 37° C. At the other extreme, *M. xenopi* grows best at 42° C.

Photoreactivity

Historically, *Mycobacterium* spp. have been categorized into three groups according to their photoreactive characteristics (Box 26.4). Species that produce carotene pigment on exposure to light are photochromogens (see Fig. 26.2). Color

ranges from pale yellow to orange. Species that produce pigment in the light and the dark are scotochromogens (see Fig. 26.4). Growth temperature may influence the photoreactive characteristics of a species. Pigment production is oxygen dependent, so it is important that tube caps are loose. Other species, such as *M. tuberculosis*, are nonchromogenic or non-photochromogenic (see Fig. 26.1). These colonies are a buff (tan) color and are nonphotoreactive; exposure to light does not induce pigment formation.

Biochemical identification

A panel of biochemical tests can identify most mycobacteria isolates, but because growth of most clinically significant *Mycobacterium* spp. is so slow, accomplishing this can take several weeks. Progress in molecular technology has diminished the frequency with which biochemical tests are routinely performed in the identification of mycobacteria. Because mycobacterial species may show only quantitative

Fig. 26.7 Schematic diagram for the identification of rapidly growing *Mycobacterium* spp. Exceptional reactions occur. Organisms should be subjected to a battery of morphologic and physiologic tests before final identification is made. *LJ*, Löwenstein-Jensen medium.

^cYoung cultures may be nonchromogenic

differences in the enzymes used in biochemical identification, no single biochemical test should be relied on for the identification of a species. For expediency, all necessary biochemical tests should be set up at one time. The biochemical tests are based on enzymes that the organisms possess, the substances that their metabolism produces, and the inhibition of growth on exposure to selected biochemicals.

Niacin accumulation

Most mycobacteria possess the enzyme that converts free niacin to niacin ribonucleotide. However, 95% of *M. tuberculosis* isolates produce free niacin (nicotinic acid) because this species lacks the niacin-connecting enzyme. Accumulation of niacin, detected as nicotinic acid, was the most used biochemical test for the identification of *M. tuberculosis*. Nicotinic acid reacts with cyanogen bromide in the presence of an amine to form a yellow-pigmented compound. Reagent-impregnated strips eliminated the need to handle and dispose of cyanogen bromide, which is caustic and toxic. Because of molecular assays, this test is rarely used today.

The niacin test may be negative when performed on young cultures with few colonies. It is recommended that the test be done on egg agar cultures 3 to 4 weeks old (results are most consistent when the test is performed on egg-based media) and with at least 50 colonies. Tests that yield negative results may need to be repeated in several weeks. The test should not be performed on scotochromogenic or rapidly growing species because *M. simiae*, the BCG strain of *M. bovis*, *M. africanum*, *M. marinum*, *M. chelonae*, and *M. bovis*, may be positive, although this rarely occurs.

Nitrate reduction

The production of nitroreductase, which catalyzes the reduction of nitrate to nitrite, is relatively uncommon among *Mycobacterium* spp., but a positive result may be seen in *M. kansasii*, *M. szulgai*, *M. fortuitum*, and *M. tuberculosis*. Bacteria are incubated in 2 mL of sodium nitrate at 37° C for 2 hours. Hydrochloric acid (1:1 dilution in water), sulfanilamide, and

N-naphthylethylenediamine dihydrochloride are then added; if the bacteria reduce the nitrate to nitrite, a red coloration occurs (Fig. 26.8). When no color change develops, however, either no reaction occurred, or the reaction has gone beyond nitrite. The addition of zinc detects nitrate and results in a color change to pink in a true-negative reaction. Commercially available strips have simplified the assay. The nitrate reduction test differentiates *M. tuberculosis* from the scotochromogens and MAC.

Catalase

Catalase is an enzyme that splits hydrogen peroxide into water and oxygen. Mycobacteria are catalase positive. However, not all strains produce a positive reaction after the culture has been heated to 68° C for 20 minutes. Isolates that are catalase positive after heating have a heat-stable catalase (Fig. 26.9). Most MTBC organisms do not produce heat-stable catalase; exceptions are strains resistant to isoniazid. Other heat-stable, catalase-negative species include *M. gastri*, *M. haemophilum*, and *M. marinum*. Semi-quantitation of catalase production is based on the addition of Tween 80 (a detergent) and hydrogen peroxide to a 2-week-old culture grown in an agar deep. The reaction is read after 5 minutes, and the resulting column of bubbles is measured (Fig. 26.10). The column size is recorded as greater than or less than 45 mm.

Hydrolysis of Tween 80

Some mycobacteria possess a lipase that can split the detergent Tween 80 into oleic acid and polyoxyethylated sorbitol. The pH indicator neutral red is initially bound to Tween 80 and has an amber color. After hydrolysis of Tween 80, neutral red can no longer bind, and it is released, causing pink

coloration. The time required for the hydrolysis is variable. Results are recorded as positive after 24 hours, 5 days, or 10 days. This test is helpful in distinguishing between scotochromogenic and nonphotochromogenic mycobacteria.

Iron uptake

Some mycobacteria can convert ferric ammonium citrate to an iron oxide. After growth of the isolate appears on an egg-based medium slant, rusty brown colonies appear in a positive reaction on the addition of 20% aqueous solution of ferric ammonium citrate; coloration is the result of iron uptake (Fig. 26.11). The test is most useful in distinguishing *M. chelonae*, which is generally negative for iron uptake, from other rapid growers, which are positive.

Fig. 26.10 Semi-quantitative catalase test.

Fig. 26.8 Nitrate reduction test.

Fig. 26.9 Catalase test.

Fig. 26.11 Iron uptake.

Arylsulfatase

Most members of the genus *Mycobacterium* possess the enzyme arylsulfatase. This enzyme hydrolyzes the bond between the sulfate group and aromatic ring structure in compounds with the formula $R-OSO_3H$. Tripotassium phenolphthalein sulfate is such a molecule, from which phenolphthalein is liberated with exposure to arylsulfatase. The liberation of phenolphthalein causes a pH change in the presence of sodium bicarbonate, indicated by the change to a pink coloration. The *M. fortuitum* complex, *M. chelonae*, *M. xenopi*, and *M. triviale*, have rapid arylsulfatase activity that can be detected in 3 days. *M. marinum* and *M. szulgai* exhibit activity with 14 days of incubation.

Pyrazinamidase

Pyrazinamidase hydrolyzes PZA to pyrazinoic acid and ammonia in 4 days. Ferrous ammonium sulfate combines with pyrazinoic acid, producing a red pigment (Fig. 26.12). This reaction occurs in about 4 days and may be useful in distinguishing *M. marinum* (positive) from *M. kansasii* (negative) and *M. bovis* (negative) from *M. tuberculosis* (positive).

Tellurite reduction

Reduction of colorless potassium tellurite to black metallic tellurium in 3 to 4 days is a characteristic of MAC (Fig. 26.13) and thus is useful in distinguishing MAC from other nonchromogenic species. In addition, all rapid growers can reduce tellurite in 3 days.

Fig. 26.12 Pyrazinamidase test.

Fig. 26.13 Test for tellurite reduction.

Urease

Detection of urease activity can be used to distinguish *M. scrofulaceum*, which is urease positive, from *M. goodii*, which is urease negative (Fig. 26.14). A loopful of test organism is grown in 4 mL of urea broth at 37° C for 3 days. A pink-to-red color is indicative of a positive reaction.

Inhibitory tests

Thiophene-2-carboxylic acid hydrazide

T2H distinguishes *M. bovis* from *M. tuberculosis*. *M. bovis* is susceptible to lower concentrations of T2H than *M. tuberculosis*. Variability in inhibition exists, depending on the concentration of the inhibitory agent and the temperature of incubation.

Sodium chloride tolerance

High salt concentration (5% NaCl) in egg-based media (e.g., LJ medium) inhibits the growth of most mycobacteria. *M. flavescens*, *M. triviale*, and most rapidly growing *Mycobacterium* spp. are exceptions that do grow in the presence of 5% NaCl.

Growth on MacConkey agar

The *Mycobacterium fortuitum-chelonae* complex can grow on MacConkey agar without crystal violet, whereas most other mycobacteria cannot. This is not the same formulation of MacConkey agar typically used for the isolation of enteric bacilli.

Chromatography

The cell walls of *Mycobacterium* spp. contain long-chain fatty acids called *mycolic acids*, which can be detected by chromatography. The type and quantity of mycolic acids are species specific. Identification of *Mycobacterium* spp. uses HPLC (see Chapter 11). Enough mycolic acid can easily be extracted from small quantities of bacterial cultures. A basic saponification followed by acidification and chloroform extraction allows accurate identification of most mycobacterial species using chromatograms. Species identifications made with HPLC have been shown to agree well with biochemical and nucleic acid probe identifications. Chromatography is rapid and highly reproducible, but the initial equipment cost is high. This method has largely been replaced by molecular assays and MALDI-TOF mass spectrometry.

Fig. 26.14 Urease test.

Hybridization and nucleic acid amplification tests for *Mycobacterium tuberculosis*

The use of nucleic acid hybridization techniques allows the rapid identification of several common mycobacterial species. The first commercially available nucleic acid probe was the AccuProbe (Gen-Probe, San Diego, CA). It was approved for use on culture isolates to identify the MTBC, the MAC, *M. avium*, *M. intracellulare*, *M. kansasii*, and *M. goodii*. These tests use labeled (e.g., acridine ester–labeled nucleic acid) probes specific to mycobacterial ribosomal RNA (rRNA). The rRNA is released from the cell after sonication. The DNA probe is incubated with the test solution. If specific rRNA is present, a stable DNA-RNA complex, or hybrid, is formed. Unbound probe is chemically degraded. The complex is detected by adding an alkaline hydrogen peroxide solution. The hybrid-bound acridine ester is available to cause a chemiluminescent reaction, resulting in the emission of light. The amount of light emitted is related to the amount of hybridized probe.

The sensitivity of the assay ranges from 95% to 100%, depending on the species and species complexes. The amount of organism required for testing in the case of *M. tuberculosis* is a single colony of at least 1 mm in diameter, or in the case of MAC, a barely visible film of growth on the surface of the medium. Most positive results are well above the cutoff value of 10% hybridization. When a probe is used on a contaminated specimen, the resulting hybridization percentage may incorrectly fall below accepted cutoff hybridization levels, leading to a false-negative result. DNA hybridization identification can be applied to growth on conventional agar and to growth in liquid media. The combination of broth-based growth for detection and DNA hybridization identification using the probe technology allows rapid recovery and identification.

In addition to hybridization assays, many laboratories use nucleic acid amplification tests to identify mycobacteria. The INNO-LiPA Mycobacteria v2 test (Fujirebo, Malvern, PA) is a line probe assay that targets the 16S-23S rRNA spacer region of mycobacteria and has been used to directly detect and identify the MTBC, the MAC, *M. kansasii*, *M. xenopi*, *M. goodii*, and *M. chelonae*. The GenoType Mycobacteria Direct test (Hain Lifescience, Nehrin, Germany) uses a similar format and has additional probes for *M. celatum*, *M. mageritense*, *M. peregrinum*, and *M. fortuitum*. Although these assays have not yet received FDA approval, many U.S. laboratories have validated them.

Automated DNA sequencing is the most accurate method for the identification of mycobacterial isolates. A commonly used target is the gene coding for 16S rRNA. This gene is present in all bacteria and contains conserved and variable regions. Identification is accomplished by PCR amplification of DNA, followed by sequencing of the amplicons (amplified products). The organism is identified by comparison of the nucleotide sequence with reference sequences in a quality database. Other genes targeted include the *hsp65* and *rpoB* genes. Although this method holds great promise, sequences in some reference databases are not accurate, and procedures are not yet standardized. The FDA has not approved sequence databases, but some laboratories have verified sequencing tests as laboratory-developed tests. As molecular methods became more widely available commercially, identification and detection of mycobacteria has become faster and more specific.

Direct nucleic acid amplification tests

Nucleic acid amplification assays designed to detect MTBC bacilli directly from patient sputum specimens can be performed in as little as 6 hours on processed specimens and offer the promise of same-day reporting of results for detection and identification of *M. tuberculosis*. This methodology is recommended by the CDC as a standard of practice. However, the test is only recommended on patients with signs and symptoms of TB. The Amplified Mycobacterium tuberculosis Direct test (Hologic, Marlborough, MA) consists of transcription-mediated amplification of a specific 16S rRNA target performed at a constant temperature for the detection of MTBC rRNA in smear-positive and smear-negative respiratory specimens. The Cepheid Xpert MTB/RIF (Cepheid, Sunnyvale, CA) consists of PCR amplification of the 584-base pair region of the 16S rRNA gene sequence that uses molecular beacon probes.

Mass spectrometry

MALDI-TOF mass spectrometry is becoming more commonly used in microbiology laboratories (see Chapter 11) and is used in the identification of the mycobacteria. Because of the increased risk of laboratory-acquired infections when working with the mycobacteria, the processing of these isolates for MALDI-TOF mass spectrometry is different from that for other bacteria. In addition, because of the unique cell wall of the mycobacteria, an extraction step is required before the sample is added to the target plate. MALDI-TOF mass spectrometry requires a large biomass, so subculturing is often required. Because of the slow-growing nature of the MTBC, this can take 1 to 3 weeks. Another drawback to this method is that the MTBC cannot be identified to the species level. Using customized databases, some U.S. laboratories have reported the ability to speciate some of the rapidly growing mycobacteria. The two commercially available systems, VITEK MS (bioMérieux) and the MALDI Biotyper system (Bruker Daltonics, Billerica, MA), have databases that include the MTBC and NTM. The MALDI-TOF mass spectrometry system provides accurate identification of mycobacteria from solid media. Tests from liquid media have yielded variable results.

Susceptibility testing of *Mycobacterium tuberculosis*

Along with the increased incidence of mycobacterial disease, the development of multidrug-resistant strains of mycobacteria has been observed. For patients to receive appropriate therapy, the CDC recommends that when isolated, *M. tuberculosis* be tested for susceptibility to isoniazid, rifampin, ethambutol, and streptomycin. PZA should also be considered. Similarly, testing should be repeated if the patient's cultures for *M. tuberculosis* remain positive after 3 months of therapy. Susceptibility testing of mycobacteria requires meticulous technique and experienced personnel. Therefore laboratories with few *M. tuberculosis* isolates should consider sending isolates to a reference laboratory for susceptibility testing. Currently, two main methods are used for determining antimicrobial susceptibility of MTBC: culture-based drug

susceptibility testing and molecular drug susceptibility testing. The culture-based drug susceptibility method includes the agar proportion test, two broth systems, and the Sensititre microtiter dilution method (Thermo Fisher Scientific, Waltham, MA).

The agar proportion method is commonly used in the United States and Europe for all antimycobacterial drugs except PZA. The recommended medium is Middlebrook 7H10 agar supplemented with oleic acid–albumin–dextrose–catalase medium. The agar is prepared with two different concentrations of the drugs and dispensed into quadrant Petri dishes. A bacterial suspension equal to a McFarland #1 standard is prepared. The suspension is then diluted 10^{-2} and 10^{-4} , and the dilutions are plated to separate media. The two dilutions provide a set of plates that should be countable (i.e., 100 to 300 colony-forming units [CFU] on the control plate). Plates are incubated at 37° C. A control plate is set up for each drug tested so the number of colonies on the test quadrants can be counted and compared with the number on the control quadrant. If the test growth is less than 1% of the control growth, the organism is susceptible, and if greater, it is resistant. By this method, results can be obtained in 2 to 3 weeks, depending on the growth rate of the organism. In clinical correlations with in vitro data, if greater than 1% of a patient's bacilli are resistant to a particular drug, treatment fails. The test is often referred to as the *proportion method* because it allows one to predict the probability that 1% of the cells are resistant or not.

The two FDA-approved liquid methods to determine the susceptibility of *M. tuberculosis* to antimycobacterial agents are the MGIT 960 and VersaTREK. The broth methods use the principles of the agar proportion assay and employ a continuous monitoring system providing results more quickly than the agar method. Growth is indicated by the amount of fluorescence or gas measured by the BACTEC MGIT 960 or VersaTREK culture system, respectively. For each drug tested, a standardized inoculum is added to drug-free and drug-containing vials. The growth rate in the absence or presence of drug is then compared. Because it is not necessary to wait to visually detect growth, continuous monitoring system–based susceptibility results are usually available in 3 to 13 days. This compares favorably to about 21 days for the gold standard agar proportion method.

Molecular assays for drug-resistant mycobacteria can provide results in a few hours. The Cepheid Xpert MTB/RIF, discussed earlier, can be performed on unprocessed or processed sputum samples. It not only can detect the presence of MTBC, but it also can detect five separate mutations within the *rpoB* gene that indicate rifampin resistance. The GenoType MTBDRplus VER 2.0 (Hain Lifescience) can be used on clinical samples and culture isolates. It too can identify MTBC and detect mutations indicating resistance to rifampin and isoniazid. When a mutation is found, the CDC recommends gene sequencing to confirm.

Susceptibility testing of most NTM is not performed routinely. An exception is the rapidly growing mycobacteria. Broth microdilution, agar disk diffusion, and the Etest (bioMérieux) have been used for performing susceptibility testing on the rapid growers. The Clinical and Laboratory Standards Institute published guidelines in 2003 recommending broth dilution as the reference method for NTM.

POINTS TO REMEMBER

- Mycobacteria are important causes of human diseases, such as TB and Hansen disease.
- Mycobacteria have a unique cell wall, and special stains are required to visualize the microorganisms.
- Many *Mycobacterium* spp. are environmental microorganisms infrequently isolated from clinical specimens.
- Isolation of mycobacteria requires specific safety precautions, including laboratories with negative air pressure, biological safety cabinets, the use of respirators and other PPE, and electric incinerators instead of flame incinerators.
- Most pathogenic mycobacteria are slow growers, taking up to several weeks for isolation on artificial media.
- Some *Mycobacterium* spp. produce a pigment, which can be a helpful feature in their identification.
- Other tests for identification of mycobacteria include rate of growth, nitrate reduction, niacin production, presence of heat-stable catalase, and sensitivity to T2H. However, phenotypic identification is being replaced by molecular methods such as nucleic acid amplification.
- Antimicrobial susceptibility testing of the mycobacteria, while important, is technically demanding and should be performed only by experienced personnel.

LEARNING ASSESSMENT QUESTIONS

1. Which fluorescent stain(s) can be used to detect the mycobacteria?
 - a. Auramine-rhodamine
 - b. Kinyoun
 - c. Ziehl-Neelsen
 - d. Both b and c
2. A nonpigmented mycobacterium is isolated that reduces nitrate to nitrite and is niacin positive. Which organism would you suspect?
 - a. *Mycobacterium kansasii*
 - b. *Mycobacterium xenopi*
 - c. *Mycobacterium tuberculosis*
 - d. *Mycobacterium avium* complex (MAC)
3. Which statement is correct regarding the causative agent of Hansen disease?
 - a. It is highly contagious.
 - b. It readily grows on most mycobacterial media.
 - c. It grows best at core body temperature (37° C).
 - d. It does not grow in vitro.
4. The skin test for tuberculosis is characterized by which of the following?
 - a. Detects antibodies to mycobacterial antigens
 - b. Detects a cell-mediated immune response to mycobacterial antigens
 - c. Uses the bacillus Calmette-Guérin (BCG) strain as the antigen source
 - d. Both a and b
5. When hired to work in the mycobacteriology laboratory, a laboratory scientist had a nonreactive PPD skin test. Six months later, his PPD skin test was reactive. What does this likely indicate?
 - a. It was a false-positive result.
 - b. Tuberculosis was acquired before his hire.

- c. He acquired *Mycobacterium tuberculosis* infection between the first and second skin test.
- d. Not enough information is provided to determine.
6. A primary care provider suspects a patient has a mycobacterial soft tissue infection. At which temperature should the inoculated media be incubated?
 - a. 4° C
 - b. 28° C
 - c. 35° C
 - d. 42° C
7. When trying to isolate *Mycobacterium* spp., which of the following specimens should be decontaminated before plating?
 - a. Sputum
 - b. Lung biopsy
 - c. Lymph node biopsy
 - d. Pleural fluid
8. A physician provides material from a patient with a skin infection that has spread to the bone. After 3 days of incubations at 35° C on Middlebrook 7H10 medium, small, off-white colonies are seen. Which of the following organisms would you suspect?
 - a. *Mycobacterium ulcerans*
 - b. *Mycobacterium chelonae*
 - c. *Mycobacterium fortuitum* group
 - d. *Mycobacterium avium* complex
9. Microscopic examination of material from a cervical lymph node taken from a child with lymphadenitis reveals acid-fast bacilli. Which of the following organisms would you suspect?
 - a. *Mycobacterium bovis*
 - b. *Mycobacterium kansasii*
 - c. *Mycobacterium genavense*
 - d. *Mycobacterium avium* complex
10. What are the current recommendations for the identification of *Mycobacterium tuberculosis* in the clinical laboratory?
11. Why should mycobacterial infections be treated for 6 months or longer, and why is there a need to use multiple drugs when treating *M. tuberculosis* infections?
12. How do the various levels of mycobacterial laboratory testing differ, and why should smaller-volume laboratories consider not performing full identification and susceptibility testing on mycobacterial isolates?
13. What are the methods used to process clinical specimens for mycobacterial culture and the reasons specimens must be decontaminated and digested before culture?
14. With respect to laboratory technique in the isolation and identification of mycobacteria, what are some causes of false-negative and false-positive results?
15. What are the important safety considerations for laboratories attempting mycobacterial isolation and identification?

Bibliography, 637

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics and structures of fungi.
2. Compare the cellular characteristics and morphology of fungi (eucaryotes) and bacteria (procaryotes).
3. Compare asexual and sexual reproduction of fungi.
4. List the divisions of fungi.
5. Identify the major causes of fungal infections.
6. Describe the common opportunistic saprobes associated with infections in immunocompromised hosts.
7. Characterize the following different types of mycoses, including the tissues they affect:
 - a. Superficial
 - b. Cutaneous
 - c. Subcutaneous
 - d. Systemic
 - e. Opportunistic saprobes
8. Analyze the appropriate specimen collection procedures, staining methods, and culture techniques used in the mycology laboratory.
9. Describe the key characteristics associated with the identification of the clinically significant fungi.
10. Evaluate the methods used to identify fungi.
11. Differentiate chromoblastomycosis from eumycotic mycetoma.
12. Develop a laboratory protocol for the identification of the clinically significant yeast.

KEY TERMS

Anamorph
Arthroconidium
Ascospores
Ascus
Blastoconidium
Conidium
Dermatophytes

Dimorphic fungi
Eumycotic mycetoma
Germ tube
Hyphae
Macroconidium
Microconidium
Mold

Mycelia
Mycoses
Onychomycosis
Polymorphic fungi
Pseudo-germ tube
Pseudohyphae
Rhinocerebral mucormycosis
Rhizoids

Saprobe
Sporangiophores
Sporangiospores
Synanamorphs
Teleomorph
Thrush
Yeast

Case in point

A 32-year-old female patient developed a fever 12 days after bone marrow transplantation. Broad-spectrum antimicrobial therapy was initiated, but the fever persisted. On day 17, the patient developed skin lesions across her body and lower extremities; a biopsy was performed. Microscopic evaluation of the tissue revealed hyphal elements. That same day, after 4 days of incubation, the patient's blood cultures were positive with a yeastlike colony. Although antifungal therapy was initiated, the patient died on day 22.

Issues to consider

After reading the patient's case history, consider:

- The fungi most likely to be implicated in this patient's infection
- Steps the laboratory will use to resolve the discrepancy between what is seen in the tissue slides and what grows from the blood culture
- The steps necessary to arrive at a final identification of this agent of disease

Fungi constitute an extremely diverse group of organisms and are generally classified as **molds** or **yeasts**. Some have been recognized as true pathogens, whereas others are only known as environmental **saprobies**, living on nonliving material. Fungi can cause mild infections, trigger allergic reactions, including asthma, and produce serious life-threatening disease. With the widespread use of chemotherapy, radiation therapy, and diseases such as acquired immunodeficiency syndrome (AIDS) that affect the immune system, the line between pathogen and saprobe has been blurred. The isolation of all organisms, especially in the immunocompromised patient, must initially be considered a significant finding and evaluated in light of the patient's history and physical examination results.

General characteristics

The characteristics of fungi differ from those of plants or bacteria. Like plants, fungi are eukaryotic; they possess a true nucleus, with a nuclear membrane and mitochondria whereas bacteria are prokaryotic, lacking these structures. Unlike plants, fungi lack chlorophyll and must absorb nutrients from the environment. In addition, fungal cell walls are made of chitin, whereas those of plants contain cellulose. Most fungi are obligate aerobes that grow best at a neutral pH, although they tolerate a wide pH range. Moisture is necessary for growth, but spores and conidia survive in dry conditions for extended lengths of time.

Yeasts versus molds

Yeasts are single vegetative cells that typically form a smooth, creamy, bacterial-like colony without aerial hyphae. Because their macroscopic and microscopic morphologies are similar, identification of yeasts is based primarily on biochemical testing and molecular diagnostic methods. Yeasts reproduce by budding or fission. Budding involves maturation of the bud to an independent **blastoconidium** (daughter cell), as shown in Fig. 27.1. This process involves lysis of the yeast cell wall so that a blastoconidium can form. As this structure enlarges, the nucleus of the parent cell undergoes mitosis. Once the new nucleus is passed into the daughter cell, a septum forms and the daughter cell breaks free. During fission, two cells of equal size are formed. These cells continue to grow from the tips of the cell and divide only after a medial fission is formed.

Most molds have a fuzzy or woolly appearance because of the formation of **mycelia** (Fig. 27.2). Mycelia are made up of many long strands of tubelike structures called **hyphae**, which are either aerial or vegetative. Aerial mycelia extend above the surface of the colony and are responsible for the fuzzy appearance. In addition, aerial mycelia support the reproductive structures that produce conidia. Conidia, in many cases, are used to identify different fungal genera. The vegetative mycelia extend downward into the medium to absorb nutrients.

Microscopic appearance often aids in the identification of molds. In some species, antler, racquet, rhizoid, or spiral hyphae are formed (Fig. 27.3A). Antler hyphae have swollen, branching tips that resemble moose antlers. Racquet hyphae contain enlarged, club-shaped areas. Spiral hyphae are tightly coiled. Rhizoids (see Fig. 27.3B), rootlike structures, might be seen in some members of the order Mucorales, the causative agents of mucormycosis, and their presence and placement can assist with identification. Frequently, when fungal hyphae are being described, they are referred to as *septate* or *sparsely septate*. Septate hyphae show frequent cross-walls occurring perpendicular to the outer walls of the hyphae (Fig. 27.4A), whereas sparsely septate hyphae have few cross-walls at irregular intervals (see Fig. 27.4B). The term *aseptate*, which means absence of septations, has historically been used to describe the hyphae of members of the order Mucorales. Microscopic examination of hyphae associated with the

Fig. 27.1 Formation of blastoconidia in yeasts.

Fig. 27.2 Aerial mycelia give molds the “woolly” appearance. Vegetative mycelia are responsible for absorbing nutrients from the medium.

Fig. 27.3 **A**, Specialized structures formed in vegetative mycelia by certain fungal species. **B**, *Rhizopus* spp., showing rhizoids (unstained, $\times 200$).

Fig. 27.4 **A**, *Phaeoacremonium* sp. displaying septate hyphae (unstained, $\times 200$). **B**, Mucorales hyphae in tissue appears sparsely septate (Gomori methenamine silver stain, $\times 400$).

Mucorales often reveals occasional septations; therefore these hyphae are more correctly termed *sparsely septate* as opposed to *aseptate*.

Hyaline versus phaeoid

Another useful characteristic in identification is pigmentation. Hyaline (moniliaceous) hyphae are nonpigmented or lightly pigmented, whereas phaeoid (dematiaceous) hyphae are darkly pigmented (Fig. 27.5) because of the presence of melanin in the cell wall. Depending on the amount of melanin present, the hyphae will appear pale to dark brown or almost black. Note that the dark hyphae seen in the tissue section in Fig. 27.4B is dark colored; however, it is because of the stain that enhances visualization of fungal elements in tissue and not because of melanin. All fungal elements appear black when Gomori methenamine silver (GMS) stain is used.

Fig. 27.5 *Bipolaris* sp. is an example of a phaeoid fungus. Note the dark pigmentation, which is caused by the presence of melanin in the cell wall (unstained, $\times 200$).

Another stain that is often used to determine hyphal pigmentation in tissue is the Fontana-Masson stain. This stain specifically stains melanin, causing phaeoid hyphae to appear brown, whereas hyaline hyphae stain pink to red.

Dimorphism and polymorphism

The term *dimorphism* refers to the ability of some fungi to exist in two forms, dependent on growth conditions. **Dimorphic fungi** include a mold phase and a yeast or spherule phase. The yeast or tissue state is seen *in vivo* or when the organism is grown at 37°C with increased concentration of carbon dioxide (CO₂). The mold phase is seen when the organism is grown at room temperature (22° to 25°C) in ambient air conditions. Thermally dimorphic fungal species associated with human disease include *Blastomyces* spp., *Coccidioides immitis/posadasii*, *Histoplasma* spp., *Paracoccidioides* spp., *Sporothrix* spp., and *Talaromyces* (formerly *Penicillium*) *marneffeii*. Several other fungi also possess this ability but have not been described as agents of human **mycoses** (infections caused by fungi). **Polymorphic fungi** have both yeast and mold forms in the same culture. This characteristic occurs despite growth conditions and is best observed in *Exophiala* spp., in which the yeast phase is typically observed initially, followed by the mold phase as the colony ages.

Reproduction

Fungi can reproduce asexually (imperfect) or sexually (perfect). Asexual reproduction results in the formation of conidia (singular, **conidium**) following mitosis. Asexual reproduction is carried out by specialized fruiting structures known as *conidiogenous cells*. These structures form conidia, which contain all the genetic material necessary to create a new fungal colony. Two common conidiogenous cells are the phialides and annellides. Phialides are vase-like structures that produce phialoconidia (Fig. 27.6), whereas annellides are ringed structures that produce annelloconidia. Both form their conidia blastically (budding) like many yeasts; the parent cell enlarges, and a septum forms to separate the conidial cell. Another type of conidia is the arthroconidia (singular, **arthroconidium**). These conidia are formed by fragmentation of fertile hyphae as opposed to being formed by conidiogenous cells (Fig. 27.7).

In the clinical laboratory, mold identifications may be based on microscopically observing structures formed as a result of asexual reproduction. Sexual reproduction requires the joining of two compatible nuclei, followed by meiosis (Fig. 27.8). A fungus that reproduces sexually is known as a **teleomorph**.

Fig. 27.6 An example of asexual reproduction is the production of phialoconidia. Conidia are formed from conidiogenous cells such as phialide (a vase-like structure). Phialoconidia are “blown out” of the phialide.

Fig. 27.7 In another form of asexual reproduction, arthroconidia are formed by fragmentation of fertile hyphae.

Fig. 27.8 Sexual reproduction occurs by the fusion of compatible nuclei and subsequent production of a zygospore.

Occasionally, these fungi will also reproduce asexually. When this occurs, the asexual form is termed the **anamorph**. If more than one anamorph is present for the same teleomorph, the anamorphic strains are termed **synanamorphs**.

Taxonomy

There are over 100,000 named fungal species and an estimated 1 million to 10 million undiscovered species. Most causative agents of clinical infections are found in four groups of fungi. They consist of the phyla Ascomycota and Basidiomycota, subphylum Mucoromycotina, and the form division Fungi Imperfecti (Deuteromycota).

Ascomycota

Approximately 50% of all named fungi are classified in the phylum Ascomycota. Fungi associated with the phylum Ascomycota are characterized by the production of sexual spores known as **ascospores**. Ascospores are formed within a sac-like structure known as an **ascus** (plural, asci). It is important to note, however, that they are usually identified on the basis of characteristic asexual structures. Representative organisms include *Microsporum* spp., *Trichophyton* spp., and *Scedosporium* spp. Phylogenetically, the genus *Candida* belongs to the phyla Ascomycota. However, many *Candida* species do not have a teleomorph; therefore they are categorized as Fungi Imperfecti.

Basidiomycota

Only a few members of the phylum Basidiomycota are clinically significant. The major pathogens are members of the *Cryptococcus neoformans* and *C. gattii* species complexes. Members of the genera *Malassezia*, *Trichosporon*, and *Rhodotorula* are also associated with human infections. Basidiomycetous molds are being recovered in increasing numbers in the laboratory, but their clinical significance is not clearly understood. Close communication between the physician and the laboratory would help determine whether the isolate is an environmental contaminant or an agent of disease.

When basidiomycetous molds are recovered in the laboratory, they typically remain sterile, complicating the identification process. One clue that a mold is a basidiomycete is the presence of clamp connections. Clamp connections occur at the septations in the vegetative hyphae and are easily visible under a light microscope. A portion of the hypha on one side of the septation grows out and connects to the hypha on the other side of the septation, thereby bypassing the septation. Clamp connections are not always present. Staining with diazonium blue B or growing on culture medium supplemented with benomyl can assist in the identification of a putative basidiomycete isolate.

Mucorales

The traditional Zygomycota have undergone taxonomic changes. Taxa traditionally placed in the phylum Zygomycota are now assigned among the phyla Mucoromycota, Basidiobolomycota, and Entomophthoromycota, subphyla Mucoromycotina, Basidiobolomycotina, and Entomophthoromycotina, respectively. The most clinically significant species belong to the subphylum Mucoromycotina consisting of the orders Mucorales, Umbelopsidales, and Endogonales and includes the genera *Actinomucor*, *Apophysomyces*, *Cokeromyces*, *Cunninghamella*, *Lichtheimia* (formerly *Absidia*), *Mucor*, *Rhizomucor*, *Rhizopus*, *Saksenaea*, and *Syncephalastrum*. Members of the order are rapidly growing organisms normally found in soil. They are often opportunistic pathogens in immunocompromised hosts. The clinical infection is referred to as *mucormycosis*.

Mucorales, the most clinically significant order, generally produce profuse, gray-to-white, aerial mycelia characterized by the presence of hyaline, sparsely septate hyphae. Asexual reproduction is characterized by the presence of **sporangiophores** and **sporangiospores**. The asexual spores (sporangiospores) are produced in a structure known as a *sporangium*, which develops from a supporting structure termed a *sporangiophore* (Fig. 27.9). Although some Mucorales are capable of sexual reproduction resulting in the production of zygospores, these structures are not routinely seen in clinical laboratories.

Fungi imperfecti

The form division Fungi Imperfecti contains the largest number of organisms that are causative agents of mycoses, including cutaneous, subcutaneous, and systemic diseases. Organisms are placed within this group when no mode of sexual reproduction has been identified. Therefore they are

Fig. 27.9 Asexual reproduction by *Mucorales* is characterized by the production of spores (sporangiospores) from within a sporangium.

Fig. 27.10 The layers of skin and tissues in which fungal infections can occur.

identified on the basis of characteristic asexual reproductive structures.

Mycoses

Mycoses (singular, mycosis) are diseases caused by fungi. Fungal disease is frequently categorized on the basis of the site of the infection—superficial, cutaneous, subcutaneous, and systemic mycoses. Fig. 27.10 shows the different layers of tissues, which helps to classify infections of the skin, depending on where the infection occurs. Infections not involving the skin or deeper tissues just under the skin are termed *systemic*. Superficial and cutaneous mycoses are caused by fungi that can degrade keratin (dermatophytes) and fungi that cannot degrade keratin.

Superficial mycoses

Superficial mycoses are infections confined to the outermost layer of skin or hair. Because infections of skin, hair, and nails were at one time believed to be the result of burrowing worms that formed ring-shaped patterns in the skin, the term *tinea* (Latin, meaning “worm”) was applied to each disease, along with the Latin term for the body site. An example of nondermatophytic tinea is the disease tinea versicolor (pityriasis versicolor). This disease is characterized by discoloration or depigmentation and scaling of skin and is caused by the yeast *Malassezia furfur* complex. The disease becomes apparent in individuals with a dark complexion or in those who do not tan normally.

Another nondermatophytic superficial infection is tinea nigra. This disease is almost always caused by *Hortaea werneckii* and is characterized by brown or black macular patches, primarily on the palms. Biopsy and culture of the site are important to distinguish this infection from melanoma, a much more serious nonfungal disease. Another superficial infection, piedra, is confined to the hair shaft and is characterized by nodules composed of hyphae and a cementlike substance that attaches it to the hair shaft. Black piedra is caused by *Piedraia hortae*, and white piedra is caused by *Trichosporon ovoides* and *T. inkin*. Onychomycosis, caused by *Onychocola canadensis* and *O. kanei*, is also a nondermatophytic superficial mycosis characterized by white superficial and distal lateral subungual infections of the great toenail.

Cutaneous mycoses

Dermatormycoses are defined as fungal diseases of the keratinized tissues of humans and other animals. Although nondermatophyte species are capable of causing similar infections, this syndrome is usually a result of infection with a dermatophyte—hence, the term *dermatophytosis*. Note that this term should not be used until the causative agent has been identified as a dermatophyte. Genera in this group include *Trichophyton*, *Microsporum*, and *Epidermophyton*. Dermatophytic infections usually involve a restricted region of the host; traditionally, these diseases are named with respect to the portion of the body affected. The various forms of ringworm continue to be described in these terms, as shown in Table 27.1.

Table 27.1 Various forms of dermatophytoses and their respective affected sites	
Type of ringworm	Site affected
<i>Tinea capitis</i>	Head
<i>Tinea favosa</i>	Head (distinctive disease)
<i>Tinea barbae</i>	Beard
<i>Tinea corporis</i>	Body (glabrous skin)
<i>Tinea manuum</i>	Hand
<i>Tinea unguium</i>	Nails
<i>Tinea cruris</i>	Groin
<i>Tinea pedis</i>	Feet
<i>Tinea imbricate</i>	Body (distinctive lesion)

Each ringworm lesion is the result of local inoculation of skin with the causative agent. Lesions enlarge with time, usually with most inflammation occurring at the advancing edge of the lesion. However, some cases of ringworm are subclinical, exhibiting only a dry, scaly lesion without inflammation. Symptoms of cutaneous mycoses include itching, scaling, or ringlike patches on skin; brittle, broken hair; and thick, discolored nails.

Subcutaneous mycoses

Subcutaneous mycoses involve the deeper skin layers as well as muscle, connective tissue, and bone. Except in certain patient populations, dissemination through the blood to major organs does not occur. Characteristic clinical features include progressive, nonhealing ulcers and the presence of draining sinus tracts. In tropical areas, some agents, such as *Phialophora* spp. and *Cladosporium* spp., cause chromoblastomycosis, which is characterized by verrucous nodules that often become ulcerated and crusted. This disease is diagnosed by the presence of characteristic lesions accompanied by microscopic sclerotic bodies, often referred to as “copper pennies” because of their shape and staining properties in tissue sections.

Eumycotic mycetoma is caused by fungi and results in draining sinus tracts and tissue destruction. Grains (granules), which are tightly bound hyphae, can be collected from the fluids that drain from the sinus tracks and are useful in identifying the causative agent. The disease can be cutaneous or subcutaneous. Worldwide, about 40% of mycetomas are eumycotic, and the rest are actinomycotic, caused by *Actinomycetes* bacteria (see Chapter 16).

Sporotrichosis, caused by the *Sporothrix schenckii* species complex, commonly presents as a progressive lymphocutaneous infection, beginning with a single draining lesion and progressing along the limbs via the lymphatic system, forming multiple draining lesions. However, granules are not formed, thus this infection does not qualify as a mycetoma. Dissemination of these species causing systemic sporotrichosis is much more common, and *Sporothrix* has been implicated in pneumonia that is refractory to antifungal therapy.

Systemic mycoses

Systemic, or disseminated, mycoses are infections that affect internal organs or deep tissues of the body. Frequently, the initial site of infection is the lung, from which the organism disseminates hematogenously to other organs, including skin. Generalized symptoms include fever and fatigue. Chronic cough and chest pain might also accompany these infections. Historically, the term *systemic mycoses* was used to describe diseases caused by thermally dimorphic fungi, including *Histoplasma*, *Coccidioides*, and *Blastomyces* spp. However, other fungal agents are also capable of causing systemic disease, including but not limited to *Aspergillus*, *Fusarium*, *Scedosporium*, and *Curvularia* spp. as well as some yeasts, such as *Candida* and *Cryptococcus* spp. It is important to note that any fungus is capable of disseminating from the primary site of infection in the immunocompromised host.

Clinically significant species

Agents of superficial mycoses

Superficial mycoses are fungal diseases that affect only the cornified layers (stratum corneum) of the epidermis. Patients who have superficial fungal infections do not show any overt symptoms because the fungal agents do not activate any tissue response or inflammatory reaction. Patients usually seek medical attention to address cosmetic rather than medical concerns caused by these fungi.

Malassezia furfur

Clinical manifestations

The *Malassezia furfur* complex causes tinea versicolor, a disease characterized by patchy lesions or scaling of varied pigmentation. It is also thought to be a cause of dandruff. Lesions associated with tinea versicolor typically appear as pale patches in individuals with darkly pigmented skin, but they can also be described as fawn-colored liver spots in individuals with a fair complexion. Lesions become especially evident in warm months, when sun exposure is more likely. Tinea versicolor may involve any area of the body, but the most prevalent sites include the face, chest, trunk, and abdomen. Antifungal therapy is not typically indicated, but the appearance of lesions may be diminished by treatment with antidandruff shampoos. Interestingly, *M. furfur* complex has also been implicated in disseminated infections in patients receiving lipid replacement therapy (total parenteral nutrition), particularly in infants. Removal of indwelling feeding lines is usually sufficient to clear infections without using antifungal therapy.

M. furfur is a common endogenous skin colonizer. Although the reasons for overgrowth by *M. furfur* resulting in clinical manifestation are still unknown, it appears to be related to squamous cell turnover rates. This is evidenced by the higher incidence of tinea versicolor among persons receiving corticosteroid therapy, which decreases the rate of squamous epithelial cell turnover. Investigators have identified genetic influence, poor nourishment, and excessive sweating as other factors that contribute to the overgrowth of the organism on the skin. This organism is found worldwide, with the greatest prevalence in hot, humid, and tropical locations.

Laboratory diagnosis

M. furfur can be identified by microscopic examination of skin scrapings from characteristic lesions in a potassium hydroxide (KOH) preparation or by observing yellow fluorescence with a Wood lamp on examination of the infected body site. Microscopic examination of the direct smear in KOH preparations reveals budding yeasts, approximately 4 to 8 μm , along with septate, sometimes branched, hyphal elements. This microscopic appearance has gained *M. furfur* the nickname the spaghetti-and-meatballs fungus (Fig. 27.11).

M. furfur requires lipids for growth and will not grow on routine fungal media that have not been supplemented with a lipid source. Because of its special nutritional requirements, routine fungal cultures are negative for growth. Typical yeast-like colonies may be observed only after the culture medium has been overlaid with olive oil. Colonies are cream colored, moist, and smooth.

Fig. 27.11 The typical so-called spaghetti-and-meatballs appearance showing hypha (top arrow) and a yeast cell (bottom arrow) of *Malassezia furfur* in a potassium hydroxide preparation ($\times 400$).

Piedraia hortae

Clinical manifestations

Piedraia hortae is the causative agent of black piedra, an infection of scalp hairs. The infecting organism produces hard, dark brown to black gritty nodules that are firmly attached to the hair shaft. These nodules consist of asci (sac-like structures) containing eight ascospores. The disease is endemic in tropical areas of Africa, Asia, and Latin America.

Laboratory diagnosis

When infected hairs are removed and placed in 10% to 20% KOH, the nodules may be crushed open to reveal the asci. Thick-walled rhomboid cells containing ascospores are seen. *P. hortae* grows slowly on Sabouraud dextrose agar at room temperature. It forms brown, restricted colonies that remain sterile.

Trichosporon spp.

Clinical manifestations

Trichosporon beigelii was previously described as a human pathogen. However, examination of the genome of members of the genus has revealed that *T. beigelii* is no longer a valid species infecting humans. More than 30 distinct species exist, but *Trichosporon ovoides*, *T. asteroides*, *T. inkin*, and *Cutaneotrichosporon* (previously *Trichosporon*) *cutaneum* have been implicated in most cases of superficial mycoses. An important species in this genus is *T. asahii*, which is implicated in severe and frequently fatal disease in immunocompromised hosts. Although less frequently encountered, *T. mucoides* also causes systemic disease (meningitis) and is recovered frequently from cerebrospinal fluid (CSF). The colony resembles young colonies of *Cryptococcus neoformans* but

is easily differentiated on the basis of physiologic and morphologic characteristics. *Apiotrichum* (formerly *Trichosporon*) *mycotoxinovorans* is associated with pulmonary colonization and disease in patients with cystic fibrosis.

Trichosporon spp. are occasionally found as part of the normal skin biota and can also be isolated from animals and soil. White piedra occurs on the hair shaft and is characterized by a soft mycelial mat surrounding hair of the scalp, face, and pubic region. Members of this genus have also been recognized as opportunistic systemic pathogens. Although rare, systemic diseases caused by these fungi are frequently fatal and occur most often in immunocompromised hosts, commonly those who have hematologic disorders or malignancies or are undergoing chemotherapy. Infections in immunocompromised patients include infections of the blood, CSF, and organs. White piedra is endemic in tropical areas of South America, Africa, and parts of Asia.

Laboratory diagnosis

Trichosporon spp. grow rapidly on primary fungal media and produce arthroconidia, hyphae, and blastoconidia (Fig. 27.12). The colonies are straw- to cream-colored and yeast-like. Colonies are varied and can be smooth or wrinkled, dry or moist, and creamy or velvety in appearance. Identification to the species level is confirmed by absence of carbohydrate fermentation, use of potassium nitrate (KNO₃), assimilation of sugars, and urease positivity. Molecular and proteomic approaches, such as deoxyribonucleic acid (DNA) sequence analysis and matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry, respectively, in conjunction with biochemical reactions, lead to accurate identification of species within this genus.

Hortaea werneckii

Clinical manifestations

Tinea nigra, characterized by brown-to-black, nonscaly macules that occur most often on the palms and soles, is caused by *H. werneckii*. Obsolete synonyms for *H. werneckii* include *Phaeoannellomyces werneckii* and *Exophiala werneckii*. This disease involves no inflammatory or other tissue reaction to the infecting fungus. However, the clinical presentation is so similar to that of other conditions that misdiagnosis could occur,

resulting in unnecessary surgical procedures, especially when confused with malignant melanoma. The disease is endemic in the tropical areas of Central and South America, Africa, and Asia.

Laboratory diagnosis

Diagnosis of tinea nigra can be made by direct examination of skin scrapings placed in 10% to 20% KOH. Microscopic examination shows septate hyphal elements and budding cells (Fig. 27.13). Younger cultures are primarily composed of budding blastoconidia, whereas the older mycelial portion of the colony shows wide, profusely septate hyphae with blastoconidia in clusters. Anelloconidia are seen in older hyphal colonies. *H. werneckii* produces shiny, moist, yeastlike colonies that start with a brownish coloration that eventually turns olive to greenish black.

Agents of cutaneous mycoses

General characteristics

Three genera of fungi—*Trichophyton*, *Microsporum*, and *Epidermophyton*—are causative agents of dermatophytoses. Species within these genera, referred to as **dermatophytes**, are keratinophilic; that is, they are adapted to grow on hair, nails, and cutaneous layers of skin that contain the scleroprotein keratin. Infection of deep tissue by these fungi is rare, but occasionally extensive inflammation and nail bed involvement or disseminated disease may result.

Most agents of dermatophytoses live freely in the environment (geophilic), but a few have adapted almost exclusively to living on animals (zoophilic) or human tissues (anthropophilic), and they are rarely recovered from any other source. Distribution of these species is generally worldwide, although a few are found only in restricted geographic regions.

Dermatophytes typically form two sizes of reproductive cells, **macroconidium** or **microconidium**. Both of these are anamorphic or asexual conidia, and their distinctive size, shape, and surface features make them valuable structures for species identification. Some dermatophytes are known to also have teleomorphic stages in which ascospores are the reproductive cells. Teleomorphs in this group of organisms are not observed in routine laboratory studies of patient

Fig. 27.12 Microscopic appearance of *Trichosporon* species on lactophenol cotton blue preparation showing the presence of both blastoconidia and arthroconidia ($\times 600$).

Fig. 27.13 Microscopic structures of *Hortaea werneckii*, showing characteristic budding annelloconidia ($\times 400$). *H. werneckii* causes tinea nigra.

isolates because dermatophytes are heterothallic, requiring the combination of two distinct mating types. Although a few reference laboratories perform mating tests with known *tester strains*, this procedure is not regularly performed in clinical laboratories.

Most geophilic fungi produce large numbers of conidia and therefore are among the most readily identified species. Zoophilic dermatophytes are not commonly found living freely in soil or on dead organic substrates. They often cause infections in animals and can be spread as agents of disease in humans. Fewer conidia are produced by zoophilic fungi than by geophilic species. Although the anthropophilic species are almost always encountered as agents of human disease, the infections are seldom inflammatory. Species identification may be difficult because most anthropophilic species produce few conidia.

Not only are sites diverse on the host involved in infections, but certain species also cause distinctive lesions. The notable example is tinea imbricata, caused by *Trichophyton concentricum*. Over time, involved portions of the trunk develop diagnostically distinctive concentric rings of scaling tissue. In some forms of ringworm, a persistent allergic reaction, dermatophytid, is manifested in the formation of sterile, itching lesions on body sites distant from the point of infection. Symptoms of dermatophyte infections range from slight to moderate and occasionally severe.

Infections involving hair

Different body sites manifest different symptoms of mycoses. Infections of the scalp, in which hair follicles are the initiation sites, can be among the most severe and disfiguring forms of mycoses. Tinea favosa, or favus, begins as an infection of the hair follicle by *Trichophyton schoenleinii* and progresses to a crusty lesion made up of dead epithelial cells and fungal mycelia. Crusty, cup-shaped flakes, called *scutula*, are formed. Hair loss and scar tissue formation commonly follow.

Two distinct forms of tinea capitis—gray patch ringworm and black dot ringworm—are caused by different species of dermatophytes. Gray patch ringworm is a common childhood disease that is easily spread among children. The fungus colonizes primarily the outer portion of hair shafts, the so-called *ectothrix* hair involvement. The lesions are seldom inflamed, but luster and color of the hair shaft may be lost. *Microsporum audouinii* and *Microsporum ferrugineum* are causative agents of this disease. Black dot ringworm consists of endothrix hair involvement. The hair follicle is the initial site of infection, and fungal growth continues within the hair shaft, causing it to weaken. The brittle, infected hair shafts break off at the scalp, leaving the black dot stubs. *Trichophyton tonsurans* and *Trichophyton violaceum* are the most common fungi implicated in this form of dermatophytosis.

Infections involving nails

Onychomycosis, which is infection of the nails, is most often caused by dermatophytes but also may be the result of infection by other fungi. These nail and nail bed infections may be among the most difficult dermatomycoses to treat. Long-term, costly therapy with terbinafine or itraconazole has been considered the best treatment, but results are often unsatisfactory. There is a direct association between dermatophytic

infections of the feet or hands and infections of the nails. It is unlikely that anyone suffering from tinea pedis will escape some extent of onychomycosis. The subungual form is the most common form of onychomycosis, described as lateral, distal, or proximal. Either end of the nail is first infected, with spread continuing to the nail plate. Nails become thick, discolored, and flaky. Some common agents that infect the nails are *Trichophyton rubrum*, *T. mentagrophytes*, and *T. tonsurans*, as well as *Epidermophyton floccosum*.

Tinea pedis

Among the shoe-wearing human population, tinea pedis (athlete's foot) is a common disease. Infection arises from infected skin scales coming into contact with exposed skin via a carpet, shower floors, or other shared walking/standing surfaces where shoes are not always worn. It is believed that individuals have a genetic predisposition to developing the disease because not everyone encountering infected skin scales becomes infected. Infections within a family are common. Various sites on the foot may be involved, but tinea pedis usually affects the soles and toe webs. In more severe cases, the sole may develop extensive scaling, with fissuring and erythema. The disease may progress around the sides of the foot from the sole, giving rise to use of the term *moccasin foot*, descriptive of the appearance of the infected area. Infections of the glabrous skin range from mild, with only minimal scaling and erythema, to severely inflamed lesions.

Systemic dermatophyte infections

Immunocompromised persons may suffer systemic dermatophyte infections. Disseminated disease appears in different forms. In some patients, it manifests itself as granulomas, whereas in others, pea-sized to walnut-sized nodules can develop. Biopsy of these nodules reveals fungal elements that are easily recovered in culture. This phenomenon has been seen primarily in kidney transplant recipients and is thought to have spread from athlete's foot or onychomycosis.

Epidermophyton floccosum

Epidermophyton floccosum produces only one size of conidia described as macroconidia. The smooth, thin-walled macroconidia are produced in clusters or singly. The distal end of the conidium is broad or spatulate and reminiscent of a beaver's tail. Occasionally, conidia may be single celled, but usually they are separated into two to five cells by perpendicular cross-walls.

Colonies of *E. floccosum* are yellow to yellow-tan, flat with feathered edges, and remain small in diameter. *Epidermophyton* isolates are notorious for developing pleomorphic tufts of sterile hyphae in older cultures. *Epidermophyton* is distributed worldwide.

Microsporum canis

Macroconidia from *M. canis* are spindle shaped, with echinulate, thick walls; they measure 12 to 25 μm $\times$ 35 to 110 μm and have 3 to 15 cells (Fig. 27.14). The tapering, sometimes elongated, spiny distal ends of the macroconidia are key features

Fig. 27.14 *Microsporum canis* showing spindle-shaped, echinulate macroconidia with thick walls and tapered ends, which are key features in identification of this species (unstained, $\times 450$).

Fig. 27.15 *Nannizzia gypsea* (formerly *Microsporum gypseum*) showing fusiform, moderately thick-walled macroconidia containing several cells (lactophenol cotton blue preparation, $\times 450$).

that distinguish this species. Microconidia are abundantly formed by most isolates, and these may be the only conidia maintained in cultures that have been serially transferred. Colonies are fluffy and white, with the reverse side of the colony usually developing a lemon yellow pigment, especially on potato dextrose agar. This fungus has a worldwide distribution.

Nannizzia gypsea (formerly *Microsporum gypseum*)

The fusiform, moderately thick-walled conidia (Fig. 27.15) typical of *Nannizzia gypsea* measure 8 to $15\mu\text{m} \times 25$ to $60\mu\text{m}$ and can have as many as six cells. In some isolates, the distal end of the macroconidium might bear a thin, filamentous tail. Abundant macroconidia and microconidia produced by most isolates of this species result in a powdery, granular appearance on colony surfaces. Fresh isolates typically form tan to buff conidial masses, but this species tends to develop pleomorphic tufts of white sterile hyphae in aging cultures and after serial transfers. Abundant brown-to-red pigment can form beneath some strains, but others remain colorless. *N. gypsea* is a rapidly growing geophilic species found in soils worldwide.

Fig. 27.16 *Trichophyton mentagrophytes* showing globose, teardrop-shaped microconidia (Nomarski optics, $\times 450$).

Microsporum audouinii

A slow-growing anthropomorphic dermatophyte, *Microsporum audouinii* was responsible for most of the gray patch tinea capitis of children until a few decades ago, when *T. tonsurans* replaced it as the leading cause of scalp infection. In culture, conidia are only rarely produced. Some isolates form chlamydoconidium-like swellings terminally on hyphae. Colonies of *M. audouinii* appear cottony white and generally form little or no pigment on the reverse.

Trichophyton mentagrophytes

The microconidia (Fig. 27.16) of *Trichophyton mentagrophytes* are primarily globose but may appear tear shaped and measure 2.5 to $4\mu\text{m}$ in diameter. Microconidia are found primarily in clusters described as grapelike (“en grappe”). Macroconidia are thin walled, smooth, and cigar shaped, with four to five cells separated by parallel cross-walls. These conidia measure about $7\mu\text{m} \times 20$ to $50\mu\text{m}$ and are produced singly on undifferentiated hyphae.

Colony morphology varies with the extent of conidia production. Granular colonies are noted when abundant microconidia are formed. In the downy form, conidia are less abundant. Compared with other dermatophytes, *T. mentagrophytes* is a relatively rapidly growing fungus. This species is distributed worldwide.

Trichophyton rubrum

Although *Trichophyton rubrum* is known to produce three- to eight-celled cylindric macroconidia measuring somewhat smaller than those of *T. mentagrophytes*, these are seldom seen in clinical isolates. Typical microscopic appearance of *T. rubrum* reveals clavate- or peg-shaped microconidia (Fig. 27.17) formed along undifferentiated hyphae, and even these may be sparse. Colonies usually remain white on the surface but may be yellow to red. Most strains develop a red to deep burgundy wine-colored pigment on the reverse that diffuses into the agar. This species has a worldwide distribution.

Trichophyton tonsurans

Trichophyton tonsurans possesses microconidia that are extremely variable in shape, ranging from a round shape to a peg shape. When grown on Sabouraud dextrose agar,

Fig. 27.17 *Trichophyton rubrum* showing clavate- or peg-shaped microconidia (lactophenol cotton blue preparation, ×450).

colonies usually form a rust-colored pigment on the colony's reverse. *T. tonsurans*, which infects skin, hair, and nails, has become the leading cause of tinea capitis in children in many parts of the world, including the United States.

Agents of subcutaneous mycoses

Subcutaneous mycoses are fungal diseases that affect subcutaneous tissue. These mycoses are usually the result of traumatic implantation of foreign objects into the deep layers of skin, permitting the fungus to gain entry into the host. The causative agents responsible are organisms commonly found in soil or on decaying vegetation; thus agricultural workers are most often affected. Organisms causing subcutaneous mycoses belong to a variety of genera in the form class Hyphomycetes. Although some are moniliaceous (hyaline or light colored), many are phaeoid, producing darkly pigmented colonies and containing melanin in their cell walls. The infections are commonly chronic and usually incite the development of lesions at the site of trauma. Subcutaneous fungal infections may be grouped together by the disease processes they cause or by the causative agents involved.

Chromoblastomycosis

Also known as *verruccous dermatitis* and *chromomycosis*, chromoblastomycosis occurs worldwide but is most common in tropical and subtropical regions of the Americas and Africa. In the United States, most cases occur in Texas and Louisiana. Several organisms are responsible for the disease, and certain organisms appear to reside in specific endemic areas throughout the world. Chromoblastomycosis is caused by several infectious agents, namely, *Fonsecaea pedrosoi*, *Phialophora verrucosa*, *Cladophialophora carrionii*, and *Rhinocladiella aquaspersa*.

Clinical manifestations

Chromoblastomycosis, one of the more common subcutaneous mycoses, is a chronic infection of skin and subcutaneous tissue and develops over a period of months or, more commonly, years. It is mostly asymptomatic in the absence of secondary complications, such as bacterial infections, carcinomatous degeneration, and elephantiasis. Lesions are usually confined to the extremities, often the feet and lower legs, and are a result of trauma to these areas. Lesions of

Table 27.2 Microscopic morphology of fungi causing chromoblastomycosis

Organism	Microscopic morphology
<i>Phialophora verrucosa</i>	Conidiogenous cells, phaeoid, flask-shaped phialides, with collarettes Conidia oval, one celled, occur in balls at tips of phialides
<i>Fonsecaea pedrosoi</i>	Primary one-celled conidia formed on sympodial conidiophores Primary conidia function as conidiogenous cells to form secondary one-celled conidia Some conidia are similar to those seen in <i>Cladophialophora</i> spp., some are similar to those in <i>Rhinocladiella</i> spp., and some are similar to those in <i>Phialophora</i> spp.
<i>Fonsecaea compactum</i>	Considered conspecific with <i>F. pedrosoi</i> . Similar to <i>F. pedrosoi</i> but with more compact conidial heads Conidia are subglobose rather than ovoid
<i>Cladophialophora carrionii</i>	Erect conidiophores bearing branched chains of one-celled, brown blastoconidia Conidium close to tip of conidiophore, termed <i>shield cell</i> Fragile chains
<i>Rhinocladiella aquaspersa</i>	Conidiophores erect, dark, bearing conidia only on upper portion near the tip Conidia elliptic, one celled, produced sympodially

chromoblastomycosis frequently appear as verrucous nodules that may become ulcerated and crusted. Longstanding lesions have a cauliflower-like surface. Brown, round sclerotic bodies, which are nonbudding structures occurring singly or in clusters, are seen in tissues. These sclerotic bodies reproduce by dividing in various planes, resulting in multicellular forms. Occasionally, short hyphal elements are also seen. The presence of sclerotic bodies is diagnostic for this disease. Males are predominately infected, possibly indicating a role of sex hormones in disease development. *Fonsecaea*, *Cladophialophora carrionii*, and *Phialophora verrucosa* cause most cases of chromoblastomycosis.

Laboratory diagnosis

The microscopic morphology of each of the agents is described in Table 27.2. *P. verrucosa* and *C. carrionii* are shown in Fig. 27.18. Isolates are identified on the basis of characteristic structures, such as arrangement of conidia and the manner in which conidia are borne. Organisms causing chromoblastomycosis are darkly pigmented. Growth is moderate to slow, and colonies are velvety to woolly and gray-brown to olivaceous black. Species are not differentiated by colony morphologies because they all produce similar characteristics. Molecular approaches, such as ribosomal gene sequencing, provide accurate identification to the species level.

Eumycotic mycetomas

Mycetoma is a chronic, granulomatous infection of the subcutaneous and cutaneous tissues that arises at the site of inoculation. The disease is characterized by swelling, with characteristic exudate draining to the skin surface through

Fig. 27.18 **A**, Conidia of *Phialophora verrucosa* at the tips of phialides with collarettes (Nomarski optics, $\times 1000$). **B**, Conidial arrangement of *Cladophialophora carrionii* (lactophenol cotton blue preparation, $\times 1250$). (Courtesy Dr. Michael McGinnis.)

Table 27.3 Description of granules seen in eumycotic mycetomas

Fungus	Color	Size (mm)	Texture
<i>Scedosporium boydii</i>	White	0.5–1.0	Soft
<i>Fusarium falciforme</i>	White	0.2–0.5	Soft
<i>Madurella mycetomatis</i>	Black	0.5–5.0	Hard
<i>Trematosphaeria</i> (<i>Madurella</i>) <i>grisea</i>	Black	0.3–0.6	Soft
<i>Exophiala</i> spp.	Black	0.2–0.3	Soft

sinus tracts. Mycetomas can be caused by fungi or bacteria. Those caused by bacteria are referred to as *actinomycotic mycetomas*, and those caused by fungal agents are referred to as *eumycotic mycetomas*. Although clinical manifestations are similar for both types, the cause must be determined because the therapy for each is different.

Mycetomas occur primarily in tropical and subtropical areas but are also seen in temperate zones. The disease is endemic in India, Africa, and South America. Although mycetoma is an uncommon mycosis in the United States, the following species (in order of occurrence) are the most commonly incriminated agents: *Scedosporium boydii*, *Fusarium falciforme*, *Madurella mycetomatis*, *Trematosphaeria grisea* (formerly *Madurella grisea*), and *Exophiala* spp. Direct microscopic examination of the granules collected from the draining lesion immediately differentiates eumycotic from actinomycotic mycetomas (Table 27.3). Fig. 27.19A shows the branching filamentous rods of actinomycetes in contrast with the hyphal elements seen in eumycotic infections (see Fig. 27.19B).

Scedosporium boydii

Previously, it was thought that *Scedosporium apiospermum* was the anamorphic state of *S. boydii*, but molecular characterization has revealed that *S. boydii* and *S. apiospermum* are different species. *Pseudoallescheria boydii*, the teleomorph, and the anamorph, *S. boydii*, are the same species. Similarly, *P. apiosperma* (teleomorph) and its anamorph *S. apiospermum* are the same species. *S. boydii* produces oval conidia singly at the tips of conidiogenous cells (cells that make conidia) known as *annellides* (Fig. 27.20). The teleomorph form is noted by the

formation of cleistothecia containing ascospores (Fig. 27.21). This phenomenon occurs in fungi that are homothallic (ability of a single organism to undergo sexual reproduction without a mate). This isolate grows rapidly and produces colonies that are white to dark gray on potato dextrose agar at 22° and 35°C. Opinions regarding this fungus differ in relation to it being hyaline or phaeoid.

Fusarium falciforme

Fusarium falciforme produces mucoid clusters of single- or two-celled, slightly curved conidia borne from phialides at the tips of long, unbranched, multiseptate conidiophores. Conidia are held together in mucoid clusters at the apices of the phialides. This isolate is a hyaline, septate, filamentous mold. Colonies grow slowly and are grayish brown, becoming grayish violet.

Madurella

Madurella mycetomatis causes most cases of eumycotic mycetoma. *Madurella* spp. are phaeoid, septate fungi. Approximately 50% of the isolates of *M. mycetomatis* produce conidia from the tips of phialides, but many remain sterile. This species grows very slowly but is initially white, and becomes yellow, olivaceous, or brown, with a characteristic diffusible brown pigment with age. It grows best at 37°C, with slower growth at 40°C. DNA analysis led to the description of a new species, *Trematosphaeria grisea*, formerly named *M. grisea*.

Subcutaneous phaeohyphomycosis

Phaeohyphomycosis is a mycotic disease caused by darkly pigmented (phaeoid or dematiaceous) fungi. The term phaeohyphomycosis was coined to distinguish several clinical infections caused by phaeoid fungi from those distinct clinical entities known as *chromoblastomycosis*. In tissue, these fungi may form yeastlike cells that are solitary or in short chains or hyphae that are septate, branched, or unbranched and often swollen to toruloid (irregular or beaded). The agents responsible for these mycoses are organisms commonly found in nature, encompassing many genera of Hyphomycetes, Coelomycetes, and Ascomycetes. Fungi that appear to be regularly associated with this condition include *Exophiala* spp., such as *Exophiala dermatitidis*. A more complete list of genera

Fig. 27.19 Actinomycotic mycetoma showing fine-branching, filamentous rods in tissue sample (A), compared with the hyphal elements (hematoxylin and eosin stain $\times 1000$) (B) seen in eumycotic infections (Grocott-Gomori methenamine silver stain, $\times 1000$).

associated with subcutaneous phaeohyphomycosis is given in Box 27.1.

With most *Exophiala* spp., conidia are borne from annellides, with conidia aggregating in masses at the tips of the conidiophore, as seen in Fig. 27.22. *E. dermatitidis*, however, forms conidia at the tips of phialides (Fig. 27.23). This group of fungi produces olivaceous to black colonies that are initially yeastlike but become velvety at maturity.

Sporothrix schenckii species complex

Clinical manifestations

The most commonly seen presentation of *Sporothrix schenckii* species complex infection is lymphocutaneous sporotrichosis. This chronic infection is characterized by nodular and ulcerative lesions along the lymph channels that drain the primary site of inoculation. Less commonly seen disease states include

fixed cutaneous sporotrichosis, in which the infection is confined to the site of inoculation and mucocutaneous sporotrichosis, a relatively rare condition. Primary and secondary pulmonary sporotrichosis and extracutaneous and disseminated forms of the disease may also occur.

Members of this complex, which include *Sporothrix schenckii*, *S. mexicana*, *S. globosa*, *S. luriei*, *S. albicans*, *S. inflata*, and *S. brasiliensis*, are commonly recovered from soil and are associated with decaying vegetation. Some are distributed worldwide, especially in warm, arid areas, such as Mexico, and also in moist, humid regions, such as Brazil, Uruguay, and South Africa. In temperate countries, such as France, Canada, and the United States, most cases of sporotrichosis are associated with gardening, particularly with exposure to rose thorns (rose handler's disease) and sphagnum moss.

Laboratory diagnosis

Direct examination of tissue might reveal members of the *S. schenckii* species complex as small, cigar-shaped yeasts (Fig. 27.24A). Although the organism is occasionally seen in a Gram-stained smear, wet mounts of material are often unrewarding because of the small numbers of organisms present. Microscopic examination from culture reveals thin, delicate hyphae bearing conidia developing in a rosette pattern at the ends of delicate

Fig. 27.23 Conidia of *Exophiala dermatitidis* borne at the tips of phialides as well as the black yeast synanamorph (Nomarski optics, $\times 1250$).

Fig. 27.24 **A**, Yeast phase of *Sporothrix schenckii* showing cigar-shaped yeast cells typical of the species (Nomarski optics, $\times 625$). **B**, Mold phase of *S. schenckii* revealing hyaline conidia borne at the ends of conidiophore in "rosettes" as well as phaeoid conidia along the sides of the hyphae (Nomarski optics, $\times 625$).

conidiophores. Dark-walled conidia are also produced along the sides of the hyphae and may be more readily viewable than the rosettes in mature cultures (see Fig. 27.24B).

Because members of this complex are dimorphic, cultures are examined at 22° and 37°C. These fungi grow well on most culture media, including those containing cycloheximide. The colony morphology at 22°C can be variable. At this temperature, colonies are often initially white, glabrous, and yeastlike, turning darker and more mycelial as they mature. Demonstration of dimorphism is important for the identification of these species. To induce mycelia conversion to yeast, the fungus is inoculated onto brain-heart infusion (BHI) agar supplemented with sheep red blood cells and incubated at 37°C in a CO₂ incubator. The formation of yeast colonies may require several subcultures. Complete conversion seldom occurs, but a portion of the colony will develop yeastlike cells.

Agents of systemic mycoses

Organisms that cause classic systemic fungal diseases have historically been categorized together because they share several characteristics, such as mode of transmission, dimorphism, and systemic dissemination. Although the term *systemic* generally refers to the organisms described here, it must be understood that any fungus, in an immunocompromised host, has the potential to become invasive and disseminate to sites far removed from the portal of entry.

The morphology of the systemic dimorphic at 22°C is described in Table 27.4. Conversion to the yeast or spherule form occurs when it is incubated at 35° to 37°C on enriched media with increased concentration of CO₂ (Table 27.5). Each agent has a fairly well-defined endemic area. The diseases are contracted generally by the inhalation of infectious conidia. Table 27.6 summarizes systemic mycoses, their agents, and their characteristics. All laboratory procedures to recover and identify these agents must be performed in a biological safety cabinet.

Blastomyces

Clinical manifestations

Blastomycosis is most prevalent in middle-age men, as are other systemic mycoses, presumably because occupational and recreational exposure to soil is often greater among men.

Table 27.4 Morphology of systemic fungi^a

Fungus	Macroscopic morphology	Microscopic morphology
<i>Blastomyces dermatitidis</i> , <i>B. gilchristii</i>	Slow to moderate growth White to dark tan Young colonies tenacious, older colonies glabrous to woolly	Oval, pyriform to globose smooth conidia borne on short, lateral hyphalike conidiophores
<i>Histoplasma capsulatum</i> , <i>H. mississippiense</i> , and <i>H. ohioense</i>	Slow growth White to dark tan with age Woolly, cottony, or granular	Microconidia small, one-celled, round, smooth (2–5 μm) Tuberculated macroconidia large, round (7–12 μm) Hyphalike conidiophores
<i>Coccidioides immitis</i> , <i>Coccidioides posadasii</i>	Rapid growth White to tan to dark gray Young colonies tenacious, older colonies cottony Tend to grow in concentric rings	Alternating one-celled, “barrel-shaped” arthroconidia with disjunct cells
<i>Paracoccidioides</i> spp.	Slow growth White to beige Colony glabrous, leathery, flat to wrinkled, folded or velvety	Colonies frequently only produce sterile hyphae Fresh isolates may produce conidia similar to those of <i>B. dermatitidis</i>

^aAt 22°C.Table 27.5 Mold to yeast conversion of thermally dimorphic fungi^a

Fungus	Culture media and temperature	Yeast form
<i>Blastomyces dermatitidis</i> , <i>B. gilchristii</i>	Blood agar, 37°C	Large yeast (8–12 μm) Blastoconidia attached by broad base
<i>Histoplasma capsulatum</i> , <i>H. mississippiense</i> , and <i>H. ohioense</i>	Pines medium, glucose-cysteine-blood, or BHI agar–blood agar, 37°C	Small, oval yeast (2–5 μm)
<i>Paracoccidioides</i> spp.	BHI agar–blood agar, 37°C	Multiple blastoconidia budding from single, large yeast (15–30 μm)

BHI, Brain-heart infusion.

^a*Coccidioides immitis* and *C. posadasii* can be converted to the spherule phase in modified Converse medium at 40°C in 5% to 10% carbon dioxide. Molecular assays are preferred to this procedure in the routine clinical laboratory.

Table 27.6 Summary of systemic mycoses

Fungus	Ecology	Clinical disease	Tissue form
<i>Blastomyces dermatitidis</i> , <i>B. gilchristii</i>	Mississippi and Ohio River valleys	Primary lung Chronic skin, bone Systemic, multiorgan	Large yeast (8–12 μm) Broad-based bud
<i>Histoplasma capsulatum</i> , <i>H. mississippiense</i> , and <i>H. ohioense</i> ^a	Ohio, Missouri, and Mississippi River valleys Bird and bat guano Alkaline soil	Primary lung Asymptomatic Immunodeficient hosts prone to disseminated disease	Small, oval yeast (2–5 μm) in histiocytes, phagocytes
<i>Coccidioides immitis</i> , <i>C. posadasii</i>	Semi-arid regions—southwest United States, Mexico, Central and South America In soil	Primary lung Asymptomatic Secondary cavity Progressive pulmonary Multisystem	Spherules (30–60 μm) contain- ing endospores
<i>Paracoccidioides</i> spp.	Central and South America In soil	Primary lung Granulomatous Ulcerative nasal and buccal lesions Lymph node involvement Adrenal glands	Thick-walled yeasts (15–30 μm) Multiple buds, “mariner’s wheel”

^a*Histoplasma duboisii* is endemic in Central Africa, and *H. suramericanum* is found in South America.

Although patients with primary infection may exhibit flulike symptoms, most are asymptomatic and cannot accurately define the time of onset. When the primary disease fails to resolve, pulmonary disease may ensue, with cough, weight loss, chest pain, and fever. Progressive pulmonary or invasive disease may follow, resulting in ulcerative lesions of skin and bone. In the immunocompromised patient, multiple organ systems may be involved, and the course may be rapidly fatal.

Blastomycosis is also known as *Gilchrist disease*, *North American blastomycosis*, and *Chicago disease*. It occurs primarily in North America and parts of Africa. In the United States, *B. dermatitidis* is endemic in the Mississippi and Ohio river basins, while the recently described *B. helicus* is found primarily in the west. Sporadic point source outbreaks have also occurred in the St. Lawrence River basin. The natural reservoir has not been unequivocally established, although the organism has been recovered from soil and from some natural environments. Apparently, only a very narrow range of conditions supports its growth. In areas in which the organism appears endemic, natural disease occurs in dogs and horses, with the disease process mimicking that seen in human infections.

Several species of *Blastomyces* are now recognized, including *B. dermatitidis*, *B. gilchristii*, and *B. helicus*, among others. Morphologically, *B. dermatitidis* and *B. gilchristii* are indistinguishable. *B. gilchristii* can be identified by using the sequences of the internal transcribed spacer 2 of the nuclear ribosomal ribonucleic acid (RNA) gene. The teleomorph or sexual form of *B. dermatitidis* is named *Ajellomyces dermatitidis*. It occurs only in rigidly controlled environments by mating of isolates with tester strains to produce gymnothecia containing ascospores. This teleomorph does not occur in the routine laboratory because the species is heterothallic, requiring two mating strains to produce the sexual form.

Laboratory diagnosis

For *B. dermatitidis* and *B. gilchristii*, examination of tissue or purulent material in cutaneous skin lesions may reveal large, spherical, refractile yeast cells, 8 to 15 μm in diameter, with a double-contoured wall and buds connected by a broad base (Fig. 27.25). KOH (10%) or calcofluor white (a fluorescent dye) may be used to enhance detection of the yeast cells (Fig. 27.26). In the mold phase, conidia are borne on short lateral branches that are ovoid to dumbbell-shaped and

Fig. 27.25 Conversion of the mold phase of *Blastomyces dermatitidis* to the broad-based bud yeast form (Nomarski optics, $\times 1250$).

range in diameter from 2 to 10 μm . Because they resemble a variety of other fungi, the microconidia are not diagnostic (Fig. 27.27). An enzyme immunoassay (EIA) performed on serum and blood has a sensitivity of about 89%, but the specificity is low (79%).

In culture at 22°C, the organism can produce a variety of colony morphologies—white, tan, or brown—and may be fluffy to glabrous. Frequently, raised areas, termed *spicules*, are seen in the centers of the colonies. When grown at 37°C on suitable media, *B. dermatitidis* and *B. gilchristii* produce characteristic, broad-based, budding yeast cells. The mycelial phase of the systemic dimorphic fungi—*B. dermatitidis*, *B. gilchristii*, *Coccidioides immitis*, *Coccidioides posadasii*, *Histoplasma* spp., and *Paracoccidioides* spp.—requires confirmatory identification, typically by DNA probe and DNA sequencing. Because of low sensitivity and specificity, antigen detection methods are generally not used.

Coccidioides species

Clinical manifestations

Two very similar species that infect humans are *C. immitis* and *C. posadasii*. The inhalation of only a few arthroconidia produces primary coccidioidomycosis. Clinical infections

Fig. 27.26 Exsiccated sputum, smear, calcofluor white stain, fluorescence microscopy. Yeast (8 to 20 μm), round, thick-walled, broad-based bud. Morphology suggests *Blastomyces dermatitidis* ($\times 400$).

Fig. 27.27 Mold phase of *Blastomyces dermatitidis* grown on potato flakes agar (Nomarski optics, $\times 1250$).

include asymptomatic pulmonary disease and allergic manifestations. Allergy can manifest itself as toxic erythema, erythema nodosum (desert bumps), erythema multiforme (valley fever), and arthritis (desert rheumatism). Primary disease usually resolves without therapy and confers a strong, specific immunity to reinfection.

In symptomatic patients, fever, respiratory distress, cough, anorexia, headache, malaise, and myalgia can be present for 6 weeks or longer. The disease might then progress to secondary coccidioidomycosis, which can include nodules, cavity lung disease, and/or progressive pulmonary disease. Fewer than 3% of infected individuals develop systemic disease. Filipinos and Blacks run the highest risk of dissemination, with meningeal involvement being a common result of disseminated disease. The sex distribution ratio for clinically apparent disease has been reported to favor males. The exception is in pregnant women, in whom the dissemination rate equals or exceeds that for men.

Coccidioides spp. reside in a narrow ecologic niche known as the *Lower Sonoran life zone*, which is characterized by low rainfall and semi-arid conditions. Highly endemic areas include the San Joaquin Valley of California, the Maricopa and Pima counties of Arizona, and southwestern Texas. Outside the United States, endemic areas are found in northern Mexico, Guatemala, Honduras, Venezuela, Paraguay, Argentina, and Columbia. Because they are morphologically identical, molecular evaluation is required to differentiate *C. immitis* from *C. posadasii*. It appears that the species can be traced to specific geographic locations. *C. immitis* is encountered in the San Joaquin Valley region of California, whereas *C. posadasii* is found in the desert areas of the southwest United States, Mexico, and South America.

Laboratory diagnosis

After inhalation, the barrel-shaped arthroconidia, which measure 2.5 to 4 μm $\times$ 3 to 6 μm , round up as they convert to spherules. At maturity, the spherules (30 to 60 μm) produce endospores by a process known as *progressive cleavage*; rupture of the spherule wall releases the endospores into the bloodstream and surrounding tissues. These endospores, in turn, form new spherules (Fig. 27.28). Direct smear examination of secretions may reveal the spherules containing the endospores. Caution must be exercised when diagnosis is made by histopathologic means only. Small, empty spherules may resemble the yeast cells of *B. dermatitidis*, and the endospores

can be confused with the cells of *Cryptococcus*, *Histoplasma*, and *Paracoccidioides*. Direct antigen detection methods are limited.

Microscopic examination of the culture shows fertile hyphae arising at right angles to the vegetative hyphae, producing alternating (separated by a disjunct cell) hyaline arthroconidia (Fig. 27.29). When released, conidia have an annular frill at both ends. As the culture ages, the vegetative hyphae also fragment into arthroconidia. Although *Coccidioides* spp. do not readily convert to the spherule stage at 37°C in the laboratory, they produce a variety of mold morphologies at 22°C. Initial growth, which occurs within 3 to 4 days, is white to gray, moist, and glabrous. Colonies rapidly develop abundant aerial mycelia, and the colony appears to enlarge in a circular bloom. Mature colonies usually turn tan to brown to lavender in color.

Histoplasma

Clinical manifestations

Histoplasmosis is acquired by inhalation of the microconidia of *Histoplasma* species. The microconidia are phagocytized by macrophages in the pulmonary parenchyma. In the host with intact immune defenses, the infection is limited and is usually asymptomatic, with the only sequelae being areas of calcification in the lungs, liver, and spleen. With heavy exposure, however, acute pulmonary disease can occur. In the mild form of the disease, viable organisms remain in the host, quiescent for years, and are the presumed source of reactivation in individuals with abrogated immune systems. In immunocompromised individuals, *Histoplasma* can cause a progressive and potentially fatal disseminated disease. Chronic pulmonary histoplasmosis in patients with chronic obstructive pulmonary disease can also occur. Other various manifestations of the disease include mediastinitis, pericarditis, and mucocutaneous lesions.

Different *Histoplasma* spp. cause histoplasmosis, also known as *reticuloendothelial cytomycosis*, *Cave disease*, *Spelunker disease*, and *Darling disease*. Histoplasmosis occurs worldwide. The highest endemicity in the United States is found in the Ohio, Missouri, and Mississippi River deltas. Species include *H. capsulatum*, *H. mississippiense*, and *H. ohioense*, while *H. suramericanum* is found in South America. These organisms reside in soil with a high nitrogen content, particularly in areas

Fig. 27.28 Spherules of *Coccidioides immitis* in tissue ($\times 300$).

Fig. 27.29 Mold phase of *Coccidioides immitis*, 25°C (Nomarski optics, $\times 1250$).

Fig. 27.30 **A**, Bone marrow aspirate stained with Giemsa stain showing the yeast cells of *Histoplasma capsulatum* inside the monocytes ($\times 1200$). **B**, Tissue phase of *H. capsulatum* (Gomori methylene stain, $\times 1200$). **C**, Bronchoalveolar lavage, cytocentrifuge preparation, calcofluor white stain, fluorescence microscopy. Fluorescent yeast (2 to $4\mu\text{m}$), small, budding. Morphology suggests *Histoplasma capsulatum* ($\times 1000$).

heavily contaminated with bat and bird guano. Skin testing previously demonstrated that about 80% of the population of long-term residents in endemic areas has been infected. *H. duboisii*, endemic in Central Africa, causes a clinically distinct form of disease involving primarily skin and bones, whereas *H. capsulatum* var. *farciminosum* causes epizootic lymphangitis in horses and mules.

Laboratory diagnosis

Careful examination of direct smear preparations of specimens for histoplasmosis frequently reveals the small yeast cells of *H. capsulatum* and similar *Histoplasma* species, particularly in infections seen in immunodeficient hosts. The yeast cells measure 2 to $3\mu\text{m}$ $\times$ 4 to $5\mu\text{m}$. When smears are stained with Giemsa or Wright stain, the yeast cells are commonly seen within monocytes and macrophages, occurring in significant numbers, as shown in Fig. 27.30A. The small cells, when found in tissue (see Fig. 27.30B), resemble the blastoconidia of *Candida glabrata*, but they can be differentiated by fluorescent antibody techniques or culture (see Fig. 27.30C).

Although microconidia can resemble *Chrysosporium* spp. and the macroconidia resemble *Sepedonium* spp., both saprobes do not produce two types of conidia in a single culture, nor are they dimorphic. Conversion of the mold form to the yeast form, using BHI agar incubated at 37°C , is confirmatory for *H. capsulatum*. Although complete conversion is seldom noted, a combination of both mycelial and yeast forms is sufficient for identification. *H. capsulatum* grows as a white-to-brownish mold. Early growth of the mycelial culture produces

Fig. 27.31 Large tuberculate macroconidia of *Histoplasma capsulatum* (Nomarski optics, $\times 1250$).

round to pyriform microconidia measuring 2 to $5\mu\text{m}$. As the colony matures, large echinulate or tuberculate macroconidia characteristic for the species are formed (Fig. 27.31).

Direct antigen detection and serologic procedures for the diagnosis of histoplasmosis might be adjuncts to culture methods. Using EIA methods, *H. capsulatum* antigen can be detected from serum, CSF, and urine with a sensitivity of about 95%. Other assays include complement fixation, immunodiffusion, and latex agglutination to detect circulating antibody, along with fluorescent antibody test to detect viable or nonviable fungal elements in tissue sections. Currently,

the most useful test for rapid diagnosis of histoplasmosis is the combination of a DNA hybridization system and DNA sequencing. However, the cost of maintaining equipment for molecular procedures remains a challenge for regions with limited resources.

Paracoccidioides

Clinical manifestations

Although the primary route of infection for *Paracoccidioides* spp., which includes *P. brasiliensis*, *P. lutzii*, *P. americana*, *P. restrepiensis*, and *P. venezuelensis*, is pulmonary and infection is usually unapparent and asymptomatic, subsequent dissemination leads to formation of ulcerative granulomatous lesions of the buccal, nasal, and occasionally gastrointestinal mucosa. A concomitant striking lymph node involvement is also evident. Although *Paracoccidioides* spp. have a rather narrow range of temperature tolerance, as evidenced by its predilection for growth in cooler areas of the body (nasal and oropharyngeal), dissemination to other organs, particularly the adrenal glands, occurs with compromised host defenses. *Paracoccidioides* is the causative agent of paracoccidioidomycosis (South American blastomycosis, Brazilian blastomycosis, Lutz-Splendore-Almeida disease, paracoccidioidal granuloma), a chronic, progressive fungal disease endemic to Central and South America. Geographic areas of highest incidence are typically humid, high-rainfall areas, with acidic soil conditions.

Laboratory diagnosis

Direct microscopic examination of cutaneous and mucosal lesions demonstrates the characteristic yeast cells. The typical budding yeast measures 15 to 30 μm in diameter with multipolar budding at the periphery, resembling a mariner's wheel (Fig. 27.32). These daughter cells (2 to 5 μm) are connected by a narrow base, unlike the broad-based attachment in *Blastomyces dermatitidis*. Many buds of various sizes can occur, or there may be only a few buds, giving the appearance of a so-called *Mickey Mouse cap* to the yeast cell.

Paracoccidioides produces a variety of mold morphologies when grown at 22°C. Flat colonies are glabrous to leathery, wrinkled to folded, floccose to velvety, and pink to beige to brown with a yellowish-brown reverse, resembling those of *B. dermatitidis*. Microscopically, the mold form produces small (2 to 10 μm in diameter), one-celled conidia, generally

Fig. 27.32 Yeast phase ("mariner's wheel") of *Paracoccidioides brasiliensis* with multipolar budding (Nomarski optics, $\times 1250$).

indistinguishable from those observed with the mold phase of *B. dermatitidis* or the microconidia of *Histoplasma*. On BHI-blood agar, at 37°C, the mycelial phase rapidly converts to the yeast phase.

Talaromyces marneffei

Clinical manifestations

Talaromyces (formerly *Penicillium*) *marneffei* is unique among the *Talaromyces* spp., being dimorphic. *T. marneffei* is a common cause of systemic infection in immunocompromised patients who have visited the endemic region of Southeast Asia. This includes patients with AIDS, hematologic malignancies, or autoimmune disease and patients undergoing organ transplantations. Infections are usually disseminated, with multiple organ involvement. The fungus can be isolated from cutaneous lesions, which are frequently present in infected individuals. Disseminated disease is typically fatal. Studies showed that the fatality rate was about 28% among patients who did not have AIDS and received appropriate antifungal therapy.

Laboratory diagnosis

The yeastlike cells of *T. marneffei* can be detected in Wright-stained smears from skin lesions or biopsy specimens. The cells of *T. marneffei* resemble those of *Histoplasma*. They are oval to cylindric, measuring 3 to 6 μm long, and they may have a cross-wall. The mold form has sparse green aerial and reddish-brown vegetative hyphae and produces a red diffusible pigment. Polymerase chain reaction (PCR) tests have been described for identification confirmation. Serologic assays have been shown to be important in early diagnosis; however, they are not commercially available.

Agents of opportunistic mycoses

The terms *saprobe* and *saprophyte* have been used to describe free-living microorganisms that are present in the environment but are not typically of concern with regard to human disease. The line between saprobic and pathogenic organisms is increasingly blurred. The major reason for this development is the growing number of persons with defects in their immune system. For several decades, medical science has made advances in life-sustaining and life-lengthening treatments. As a result, a serious side effect of procedures such as organ transplantation and cancer chemotherapy is the short- or long-term insult to the host defenses. The spread of AIDS has greatly magnified the problem. Persons with AIDS constitute the prime targets for infection by a wide variety of microorganisms, including the recognized pathogenic fungi and a growing list of fungi previously regarded as harmless.

The types of disease caused by these fungi are as varied as the species, sometimes more so, because a given fungus can have multiple clinical presentations. Surgical wounds are ideal points of inoculation, allowing saprobes to become opportunistic agents of disease. Skin and nail bed infections as well as severe respiratory infections can be caused by a variety of fungi in patients with AIDS. A discussion of the most common saprobes that have been associated with opportunistic infections follows. These fungi are found worldwide in the environment and are often associated with decaying vegetation.

Fig. 27.33 *Cunninghamhamella* sp. (lactophenol cotton blue, $\times 450$).

Fig. 27.34 *Lichtheimia* sp. (Nomarski optics, $\times 450$).

Mucorales

Members of the order Mucorales are common environmental isolates associated with soil and plants. They contaminate grains, breads, and fruits and are most often associated with infections of the sinuses, lungs, and skin of immunocompromised patients. Studies have indicated an increased incidence of mucormycoses. Diabetes is a significant risk factor for these infections.

Cunninghamhamella

Cunninghamhamella spp. can be recovered from the sinuses or other organs during disseminated disease. Found worldwide, this isolate is common in the environment. Sporangioophores are erect, branching into several vesicles that bear sporangioles (Fig. 27.33), and may be covered with long, fine spines. These organisms are rapidly growing and form a cottony colony that is initially white but becomes gray with age.

Lichtheimia

Lichtheimia spp. have a predilection for vascular invasion, causing thrombosis and necrosis of the tissues. This agent, along with other fungi in the order Mucorales, is usually found in patients with poorly controlled diabetes. In this patient population, the infection usually begins in the sinuses, where conidia are inhaled and take up residence. From the sinuses, infection rapidly spreads to the orbits, face, palate, and brain. This presentation is known as **rhinocerebral mucormycosis**. Other sites of infection have been noted in patients with cancer, in whom cutaneous, subcutaneous, and systemic diseases occur. *Lichtheimia* spp. are found worldwide and are often associated with soil or decomposing organic matter.

Lichtheimia hyphae are broad and ribbonlike, with few septations (Fig. 27.34). Erect sporangioophores, solitary or in groups (slightly branched), terminate in an apophysis surrounded by a sporangium. Sporangiospores are smooth and ovoid. Internodal **rhizoids** (short, thin projections that anchor the growing cells to substratum) are present. Colonies are woolly and grow rapidly, completely covering the culture medium. Colony color is initially white, becoming gray to gray-brown with age.

Mucor

As with other Mucorales, *Mucor* spp. are associated with rhinocerebral mucormycosis in addition to disseminated disease. *Mucor* spp. are commonly isolated from the environment

Fig. 27.35 *Mucor* sp. (unstained, $\times 450$).

worldwide. Sporangiospores are formed in sporangia on erect sporangioophores (Fig. 27.35). Rhizoids, typical of some Mucorales, are absent in most *Mucor* spp. The sporangia frequently remain intact, as opposed to *Rhizopus* spp., in which the sporangia typically collapse. *Mucor* spp. grow rapidly and form cottony, dirty white colonies that become mousy brown to gray with age.

Rhizopus

Rhizopus spp. are the most common Mucorales causing human disease. These are typically involved in patients with poorly controlled diabetes, presenting as rhinocerebral mucormycosis. *Rhizopus* spp. may be refractory to treatment and may be recovered from almost any source. With worldwide distribution, this isolate is easily recovered from the environment in decaying vegetation.

Rhizopus spp. are rapidly growing and have erect sporangioophores terminating in dark sporangia and sporangiospores (Fig. 27.36). At the base of the sporangioophores are brown rhizoids. Separate clusters of sporangioophores are joined by stolons, arching filaments that terminate at the rhizoids. The sporangia are typically fragile and are not easily retained when making slide culture preparations, resulting in an umbrella-shaped structure at the end of the conidiophores. *Rhizopus* spp. produce rapidly growing, woolly colonies that cover the entire surface of the culture medium. Colonies are initially white but become gray to brown with age.

Fig. 27.36 *Rhizopus* sp. (Nomarski optics, $\times 450$).

Fig. 27.37 *Syncephalastrum* sp. (Nomarski optics, $\times 450$).

Syncephalastrum

Syncephalastrum is rarely implicated in human disease but has been documented in cutaneous infections. This fungus is found in soil and decaying vegetation. Microscopically, erect sporangiophores are noted. Each sporangiophore has a large columella on which merosporangia, containing stacks of sporangiospores, are formed (Fig. 27.37). Isolates are sometimes confused with *Aspergillus* on initial examination. Colonies are rapidly growing and are initially white and become gray with age. The growth rate is rapid, with colonies covering the entire surface of the agar.

Septate and hyaline saprobes

Aspergillus

Aspergillus spp. are ubiquitous environmental saprobes and can frequently be isolated from a number of hospital sites, including ventilation systems and food. Aspergilli are the second most commonly isolated fungus after *Candida* spp. *A. fumigatus* is the species most often seen; other commonly isolated pathogenic species include *A. flavus*, *A. terreus*, and *A. niger*. Their conidia are constantly inhaled, but they are generally readily cleared in healthy, immunocompetent individuals. Mortality from infections caused by the aspergilli remains high, especially in the immunocompromised host.

Aspergillus spp. are the most frequent cause of disease in bone marrow transplant recipients, in addition to other

Fig. 27.38 Expectorated sputum, smear, Gram stain, light microscopy. Gram-variable hyphae present (3 to $10\mu\text{m}$), septate, branched 45-degree angle. Morphology suggests *Aspergillus* spp. ($\times 1000$).

Fig. 27.39 Expectorated sputum, smear, Gram stain, light microscopy. Gram-positive conidia (2 to $4\mu\text{m}$), in chain. Morphotype suggests *Aspergillus* spp. in cavity with air interface. Impression: cavitary aspergillosis ($\times 1000$). Care must be taken not to mistake these conidia for streptococci or for yeasts (see Fig. 27.40).

transplant recipients and those with cancer. Infection is initiated following inhalation of conidia. In the lung air spaces, conidia germinate into hyphae, which invade the tissue, including blood vessels (Figs. 27.38, 27.39, and 27.40). Fungal elements are easily seen with the fluorescent calcofluor white stain (Fig. 27.41). Although not all patients have chest pain, it is not uncommon for pneumonia-like symptoms to appear. The infection easily spreads hematogenously, and it is not uncommon to find multiorgan system involvement, including the brain, liver, heart, and bone (Fig. 27.42). *Aspergillus* spp. also trigger allergic reactions and are a common cause of sensitivities to molds. Another frequent presentation is that of so-called *fungus balls* in the lungs of agricultural workers who routinely are in contact with fungal conidia from environmental sources. Chronic pulmonary aspergillosis may occur in patients with structural damage to their lungs caused by other diseases, including tuberculosis and sarcoidosis.

Aspergilli may be uniseriate or biseriate. Uniseriate species are those whose phialides attach directly to the vesicle at the end of the conidiophore. Biseriate species possess

a supporting structure called a *metula*. Metulae attach directly to the vesicle, and attached to each of the metulae are phialides (Fig. 27.43). Conidia are produced from the phialides. Other characteristics include an erect conidiophore arising from a foot cell within the vegetative hyphae. It is also important to note whether or not phialoconidia remain in long chains or are easily disturbed into individual phialoconidia (see Figs. 27.39 and 27.40). Chains of conidia can be aligned in very straight, parallel columns or in a radiating pattern around the vesicle, and the conidia may be rough or smooth.

The color of *Aspergillus* spp. colonies is derived from conidia. Colors range from black to white and include yellow, brown, green, gray, pink, beige, and tan. Some species also form diffusible subsurface pigments on a variety of media. A granular texture is seen in species with abundant conidial formation. Most known pathogens in this group form green- to tan-colored colonies. Many species of aspergilli have been implicated in human disease. Although some are easily distinguished from others, molecular and proteomic tests aid in definitive identification at the species level.

Fig. 27.40 Expectorated sputum, smear, calcofluor white stain, fluorescence microscopy, MPV. Fungal hyphae present (3 to 10 μm), septate, branched 45-degree angle. Morphology suggests *Aspergillus* spp. ($\times 400$).

Fig. 27.41 Expectorated sputum, smear, Gram stain, light microscopy. Gram-negative conidia (2 to 4 μm), sporulating (arrows) ($\times 1000$). Care must be taken not to confuse these conidia with yeast germ tubes.

Beauveria

Beauveria bassiana is a rare human isolate, uncommonly associated with keratitis. This fungus is a known insect pathogen and is found worldwide on vegetation and in soil. Abundant, single-celled, tear-shaped sympoduloconidia are formed on sympodulae, which taper extremely from a rather swollen base (Fig. 27.44). Conidiophores may cluster in some isolates to form radial tufts. Colonies are hyaline, moderately rapidly growing, fluffy colonies, sometimes developing a powdery surface reminiscent of *T. mentagrophytes*.

Fig. 27.42 Brain abscess, smear, toluidine blue stain, light microscopy. Fungal hyphae present (3 to 10 μm), septate, branched 45-degree angle. Morphology suggests *Aspergillus* spp. ($\times 400$). Impression: cerebral aspergillosis.

Fig. 27.43 *Aspergillus* sp. (Nomarski optics, $\times 450$).

Fig. 27.44 *Beauveria* sp. (Nomarski optics, $\times 450$).

Fig. 27.45 *Chrysosporium* sp. (Nomarski optics, $\times 450$).

Chrysosporium

A rare cause of disease, *Chrysosporium* spp. have been recovered from nails and skin lesions. *Chrysosporium zonatum* has been linked to pneumonia and osteomyelitis in immunocompromised patients. These organisms are found in the environment worldwide. Microscopically simple, wide-based, single-celled conidia are produced on nonspecialized cells (Fig. 27.45). The conidiogenous cell disintegrates or breaks to release conidia. Both arthroconidia and aleurioconidia may be seen. Colonies are hyaline with a moderate growth rate and with age can develop light shades of pink, gray, or tan pigment.

Fusarium

Fusarium spp. are frequently seen in mycotic keratitis. In the United States, a multistate outbreak involving more than 100 individuals wearing soft contact lenses was reported in 2006. The outbreak was associated with a particular brand of contact lens solution and occurred typically in patients who wore lenses continuously without removal for several days at a time. From 2013 to 2014, seven cases of fungemia due to *Fusarium oxysporum*, related to central line catheters, were reported in a pediatric cancer center. In bone marrow transplant recipients with infections caused by fusaria, the mortality rate approaches 100%. Unless a patient regains some cell-mediated immunity, mortality is certain because of the ability of these fungi to grow and continue to invade despite antifungal therapy. Patients present with high fever, possibly disseminated skin lesions, and in some patients, fungemia. *Fusarium* spp. can be recovered in blood culture systems. Care should be taken when reviewing positive blood cultures because isolates typically appear yeastlike on initial recovery.

Normally, abundant macroconidia with fewer microconidia are produced on vegetative hyphae (Fig. 27.46). Macroconidia are banana or canoe shaped and are formed singly, in small clusters, or clustered together in mats termed *sporodochia*. Macroconidia typically are multicelled. *Fusarium* is a rapidly growing hyaline fungus that can develop various colors with age, ranging from rose to mauve to purple to yellow.

Fig. 27.46 *Fusarium* sp. (unstained, $\times 450$).

Fig. 27.47 *Geotrichum* sp. (Nomarski optics, $\times 650$).

Geotrichum

Geotrichum has been implicated in pulmonary disease in immunocompromised patients. Microscopic evaluation reveals abundant arthroconidia formed from vegetative hyphae that occur singly or may be branched (Fig. 27.47). Colonies appear white to cream and yeastlike and can be confused with *Trichosporon* spp. Occasionally, aerial mycelia form, producing colonies that resemble those of *Coccidioides* spp.

Purpureocillium

Purpureocillium lilacinum, previously *Paecilomyces lilacinus*, has been associated with cutaneous and subcutaneous infections, in addition to pyelonephritis, endocarditis, and pulmonary infections in immunocompromised and immunocompetent patients. It was recovered in a hospital outbreak with a high rate of associated death. Microscopically, care must be taken to avoid confusion between *Purpureocillium* and *Penicillium* spp. Phialides of *Purpureocillium* are generally longer and more obviously tapered, and they may be singly formed or arranged in a verticillate pattern, on which long chains of spindle-shaped or somewhat cylindric conidia are formed (Fig. 27.48).

Purpureocillium grows rapidly and usually form flat, granular to velvety colonies in shades of tan, brownish gold, or mauve. Green or blue-green colors are not seen. Infections with *Purpureocillium* are potentially serious and difficult to treat, as *P. lilacinum* is intrinsically resistant to amphotericin B and other polyenes; care should be taken when encountering fungi that are mauve in color. Molecular testing is recommended to get a definitive species identification.

Case check 27.1

Unlike most molds, *Fusarium* spp. are commonly recovered from blood. As demonstrated in the Case in Point, care must be taken for proper diagnosis because colonies may initially appear yeastlike on subculture but rapidly become woolly in appearance as hyphae are formed.

Fig. 27.48 *Purpureocillium lilacinum* (*Paecilomyces lilacinus*) (Nomarski optics, $\times 650$).

Fig. 27.50 *Scopulariopsis* sp. (lactophenol cotton blue, $\times 450$).

Fig. 27.49 *Penicillium* sp. (Nomarski optics, $\times 650$).

Fig. 27.51 *Trichoderma* sp. (Nomarski optics, $\times 650$).

Penicillium

Because many *Penicillium* spp. are inhibited at 37°C, they do not frequently cause infections. Most reports of disease involve chronic fungal sinusitis. Ubiquitous in nature, these fungi can be recovered from any location worldwide. Conidiophores are erect, sometimes branched, with metulae bearing one or several phialides on which oval to ovoid conidia are produced in long, loose chains (Fig. 27.49). This commonly seen fungus is a rapid grower, with colonies usually in shades of green or blue-green.

Scopulariopsis* and *Microascus

Scopulariopsis and *Microascus* spp. are commonly isolated from nail specimens and have been implicated in pulmonary disease in immunocompromised patients. These fungi are recovered from the environment worldwide. Conidiophores occur singularly or can be in clusters (Fig. 27.50). Conidia are formed from annellides, which increase in length as conidia are formed. The truncate-based conidia tend to remain in chains on the annellides. *Scopulariopsis* and *Microascus* spp. grow moderately rapidly and form colonies covered by tan-to-buff conidia. Some species are phaeoid.

Trichoderma

Trichoderma spp. are emerging as pathogens that can cause a range of infections, including pulmonary and skin infections, in the immunocompromised host. This isolate is readily recovered from the environment worldwide. *Trichoderma* spp.

are rapidly growing and form hyaline hyphae that give rise to yellow-green to green patches of conidia formed on clusters of tapering phialides (Fig. 27.51). Conidia may remain clustered in balls at the phialide tips. Mature colonies are intensely green and granular, with an abundance of conidia.

Septate and phaeoid saprobes

Alternaria

Based on phylogenetic studies and morphology, *Alternaria*, which consists of several saprophytic and pathogenic species, is currently grouped into 26 sections. Although *Alternaria* spp. can be recovered from almost any source, they are primarily implicated in chronic fungal sinusitis. The disease is often misdiagnosed, and patients are often treated for an extended period for bacterial sinusitis. The infection rarely spreads beyond the sinuses in immunocompetent hosts but can be found systemically in those with immune suppression. *Alternaria* spp. are found worldwide on grasses and leaves. They have been implicated in tomato rot and are readily recovered from the environment in air-settling plates.

Microscopic evaluation reveals short conidiophores bearing conidia in chains that lengthen in an acropetal fashion (Fig. 27.52). Multicelled conidia have angular cross-walls and taper toward the distal end. *Alternaria* spp. are phaeoid, rapidly growing fungi with colonies ranging from shades of gray to brown to black.

Aureobasidium

Infections by *Aureobasidium* spp. are rare but have been traced to contaminated dialysis lines, catheters, and similar devices. This organism may be recovered from blood, tissues, and abscesses. It is recovered worldwide primarily in wet environments, such as from shower tiles and water lines.

Microscopic examination reveals hyaline hyphae giving rise to hyaline conidia directly from the vegetative hyphae. With age, phaeoid hyphae develop and break up into arthroconidia, which do not bear hyaline conidia. These arthroconidia are responsible for the darkening colony morphology. *Aureobasidium* spp. grow moderately rapidly to significantly rapidly and have a yeastlike consistency. Young cultures are off-white to pink, but they become black with age, with the production of darkly pigmented arthroconidia.

Chaetomium

Infections by *Chaetomium* organisms have been reported in the brains of patients with central nervous system disease. Several of these patients have been identified as intravenous drug abusers. These fungi are found in the environment and have a predilection for cellulose products. They have been known to devastate printed literature and library holdings and have been associated with problems in indoor air quality.

Microscopically, numerous perithecia are typically seen (Fig. 27.53). These perithecia are pineapple shaped and are ornamented with straight or curled hairs or setae. The asci contained within the perithecia are evanescent, so at maturity, the pigmented, lemon-shaped ascospores are released within the

perithecium. Colonies are moderately rapid to rapidly growing and begin dirty gray and become phaeoid with age. Some species produce a diffusible pigment that turns the agar completely red.

Cladosporium

An infrequent cause of disease, *Cladosporium* spp. are primarily recovered as laboratory contaminants. Infections are typically confined to the sinuses or following traumatic inoculation. Ubiquitous in nature, this isolate can be recovered from almost any location in the world.

Cladosporium spp. form brown to olive to black hyphae and conidia (Fig. 27.54). Conidiophores are erect and can branch into several conidiogenous cells. Spherical to ovoid conidia form blastically on the end of each previously formed conidium. Branched conidium-bearing cells may dislodge, and the three scars on each of these cells give them the appearance of a shield. Generally, conidial chains of the saprobic species break up easily, whereas those of pathogenic species remain connected. These organisms are slowly to moderately growing phaeoid fungi, with granular velvety to fluffy colonies, ranging in color from olive to brown or black.

Curvularia

Curvularia spp. isolates are usually implicated in chronic sinusitis in immunocompetent patients. Found worldwide, this fungus is frequently recovered from grass, leaves, and decaying vegetation. Multicelled conidia are produced on sympodial conidiophores (Fig. 27.55). This genus is among

Fig. 27.52 *Alternaria* sp. (unstained, $\times 450$).

Fig. 27.57 *Pithomyces* sp. (Nomarski optics, $\times 450$).

the easiest to identify because of the frequently seen crescent-shaped conidia with three to five cells of unequal size and an enlarged central cell. Several species previously classified in the genus *Bipolaris* are now considered to be members of *Curvularia*. These fungi form a rapidly growing phaeoid colony that is cottony and dirty gray to black.

Phoma

Disease caused by *Phoma* spp. is usually secondary to traumatic inoculation. *Phoma* spp. produce pycnidia, which appear as black fruiting bodies that are globose and lined inside with short conidiophores (Fig. 27.56). Large numbers of hyaline conidia are generated in the pycnidium and flow out of a small apical pore. *Phoma* spp. produce a moderately rapid growing, gray-to-brown colony.

Pithomyces

Disease caused by *Pithomyces* spp. is usually secondary to traumatic inoculation. Conidia are somewhat barrel shaped, formed singly on simple short conidiophores (Fig. 27.57). Conidia have both transverse and longitudinal cross-walls and are often echinulate. *Pithomyces* spp. produce rapidly growing phaeoid colonies.

Ulocladium

Ulocladium spp. are now classified among the sections in *Alternaria*. These species are sometimes implicated in subcutaneous infections, usually following traumatic inoculation. Conidiophores bear dark, multicelled conidia on sympodial conidiophores (Fig. 27.58). Conidia have angular cross-walls

Fig. 27.58 *Ulocladium* (lactophenol cotton blue, $\times 450$).

and, in some species, echinulate surfaces. These species are rapidly growing phaeoid fungi, forming colonies ranging in color from brown to olivaceous to black.

Agents of yeast infections

The escalating incidence of yeast and yeastlike fungi isolated from patient specimens has emphasized the importance of identifying yeast isolates to the species level. With greater immunosuppression, the variety of organisms implicated in disease also expands. *Candida albicans* is the fourth most common cause of bloodborne infection in the United States, accounting for 10% to 15% of all hospital-acquired septicemia cases. Isolation of other yeasts from clinical samples is also increasing. Infections caused by many yeasts are extremely aggressive and difficult to treat.

Yeast can be classified into one of two groups: yeasts and yeastlike fungi. Isolates that reproduce sexually, by forming either ascospores or basidiospores, are truly yeasts. Most isolates that are not capable of sexual reproduction or whose sexual state has not yet been discovered are correctly termed *yeastlike fungi*. For ease of discussion, all isolates are referred to here as *yeasts*.

General characteristics

Molds and yeasts are very different morphologically, but some of the macroscopic characteristics used as aids in identifying molds can also be used to identify yeasts. Macroscopic characteristics include color and colony texture. The color of a yeast colony ranges from white to cream or tan, with a few species forming pink- to salmon-colored colonies. Some yeast isolates, referred to as *phaeoid yeasts*, are darkly pigmented because of melanin in their cell walls. Phaeoid yeasts are associated with several species of the polymorphic fungi and are discussed elsewhere in this chapter.

The texture of the yeast colonies also differs. For example, *Cryptococcus* spp. tend to be mucoid and can flow across the plate, a trait shared by some bacteria, such as *Klebsiella* spp. Some yeasts are butterlike, and others range in texture from velvety to wrinkled. Strain-to-strain variation in texture may be noted within a species.

Candida

Candida spp. are the most notorious agents of yeast infection. Clinical disease ranges from superficial skin infections

to disseminated disease. *C. albicans* is a major cause of yeast infection in the world. It is recovered as normal biota from a variety of sites, including skin, the oral mucosa, the digestive tract, and the vagina. When host conditions are altered, however, this organism is capable of causing disease in almost any site. In individuals with an intact immune system, infections are localized and limited. One of the most widely recognized manifestations of *C. albicans* infection is thrush (oropharyngeal candidiasis), an infection of the oral mucosa. **Thrush** is also recognized as an indicator of immunosuppression. Among individuals infected with human immunodeficiency virus (HIV) and those receiving prolonged antibacterial therapy or other chemotherapeutic agents, thrush manifests itself as a serious infection capable of dissemination (Figs. 27.59 and 27.60).

Candida glabrata (synonym *Nakaseomyces glabrata*) is also a common species that causes disease and accounts for many urinary yeast isolates. It may now be second only to *C. albicans* in superficial and invasive yeast infections in North America and Europe. Infections associated with *C. glabrata* tend to be aggressive in patients with multiple comorbidities and may be difficult to treat with traditional antifungal therapy (e.g., amphotericin B and fluconazole). This organism has different sugar assimilation patterns, notably rapid assimilation of trehalose, from those of *C. albicans* and therefore can be easily differentiated.

Fig. 27.59 Bronchoalveolar lavage, cytocentrifuge preparation, Gram stain, light microscopy. Gram-positive yeast with buds. Morphotype consistent with *Candida* spp. (×1000).

Fig. 27.60 Expectorated sputum smear, Gram stain, light microscopy. Gram-positive pseudohyphae. Morphotype consistent with *Candida* spp. (×1000).

Recently, *C. auris* has emerged as a multidrug-resistant yeast linked to high mortality rates associated with healthcare-associated infections worldwide. The yeast is likely transmitted from patient to patient in health care settings and has caused several outbreaks in numerous countries. The Centers for Disease Control and Prevention (CDC) recommends that a contact prevention protocol be followed for residents in nursing homes colonized or infected with *C. auris* and that they be housed in single rooms, if available. *C. auris* has been misidentified as several other yeast species. MALDI-TOF mass spectrometry assays can identify this species.

Other notable species of *Candida* include *C. krusei* (teleomorph *Pichia kudriavzevii*) and *C. tropicalis*. In addition, *C. parapsilosis* has become a major cause of outbreaks of healthcare-associated infections. These isolates are identified by the differences in their carbohydrate assimilation patterns and other secondary testing procedures, such as MALDI-TOF mass spectrometry. Table 27.7 shows important differentiating characteristics among *Candida* spp. and other yeasts.

Cryptococcus

Cryptococcus spp. are important causes of meningitis, pulmonary disease, and septicemia. Members of the *C. neoformans* species complex (composed of *C. neoformans* and *C. deneoformans*), the most notable pathogens in this genus, is a major cause of opportunistic infection in patients with AIDS. These organisms are commonly found in soil contaminated with pigeon droppings and is most likely acquired by inhalation. Members of the *C. gattii* species complex (*C. gattii*, *C. bacillisporus*, *C. deuterogattii*, *C. tetragattii*, and *C. decagattii*) are emerging pathogens, particularly in the Pacific Northwest of the United States and Canada. Infections caused by this species are similar to those caused by *C. neoformans* species complex, targeting primarily immunocompromised patients. However, *C. gattii* can also cause disease in immunocompetent hosts, and it is important to distinguish the two species because the clinical course and treatment outcomes can be different.

Cryptococcus spp. produce a capsule (Fig. 27.61) that produces the characteristic mucoid colony. The capsule can be detected surrounding the budding yeast in CSF with the aid of India ink or nigrosin (Fig. 27.62). The background fluid is black, and clear unstained halos are seen around individual yeast cells. Because of its low sensitivity, the use of India ink preparation is being replaced by cryptococcal antigen tests.

The cryptococcal antigen assays and an easy-to-use lateral-flow assay are recommended for routine use in clinical microbiology laboratories. The antigen assays detect both *C. neoformans* and *C. gattii* species complexes in CSF and serum.

Cryptococcus spp. are noted for producing blastoconidia only, without producing true hyphae or pseudohyphae on cornmeal agar. All species of the genus are urease positive, and the nitrate reaction differs. Sugar assimilations differ among the species (see Table 27.7). It is extremely difficult to distinguish members of the *C. neoformans* and *C. gattii* species complexes from each other. A key laboratory characteristic is that members of the *C. gattii* species complex use glycine as a sole carbon and nitrogen source in the presence of canavanine, whereas *C. neoformans* does not. Canavanine glycine bromothymol blue agar is commercially available for this purpose and can be used to help differentiate between these species complexes.

Rhodotorula

Rhodotorula spp. are noted for their bright salmon pink color. They resemble the cryptococci because they bear a capsule and are urease positive. Some species are also nitrate positive. They are not common agents of disease but have been known to cause opportunistic infections.

Pneumocystis

Pneumocystis can inhabit the lungs of many mammals. *Pneumocystis carinii* was originally classified with the protozoa, but nucleic acid sequencing showed conclusively that the organism is a fungus. It is apparent from nucleic acid studies that *P. carinii* is not a single species. *P. carinii* is the

species most commonly found in rats, and *P. jirovecii* is the species most often recovered from humans.

Clinical manifestations

Pneumocystis infection is acquired early in life; serologic studies have shown that most humans have antibodies or antigens by 2 to 4 years of age. In immunocompetent individuals, infection is asymptomatic; however, in immunocompromised patients, serious life-threatening pneumonia can develop. *Pneumocystis* initially was identified as the causative agent in interstitial plasma cell pneumonia seen in malnourished or premature infants. Since the early 1980s, it has remained one of the primary opportunistic infections found in patients with AIDS. A high incidence of disease also results from the use of immunosuppressive drugs in patients with malignancies and in organ transplant recipients. Underlying defects in cellular immunity apparently make patients susceptible to clinical infection with the organism.

Patients infected with *Pneumocystis* may have nonproductive cough, difficulty breathing, and a low-grade fever. Chest x-rays can be normal or show a diffuse interstitial infiltrate. The immune response to the organism after it attaches to and destroys alveolar cells is partly responsible for this radiographic pattern. When the infiltrate is examined, it is found to contain cells from the alveoli and plasma cells.

Life cycle

Pneumocystis is a nonfilamentous fungus. Terminology referring to the various life cycle forms, however, is reflected in the fact that it was first considered a protozoan. The life cycle of *Pneumocystis* has three stages: the trophozoite, which is 1 to 5 μm in size and is irregularly shaped; the precyst, which is 5 to 8 μm in size; and the cyst, which is a thick-walled sphere of about 8 μm containing up to eight intracystic bodies.

Transmission of the organism is known to occur through the respiratory route, with the cyst being the infective stage. The spores or intracystic bodies are released from the cyst in the lung, and these trophic forms multiply asexually by binary fission on the surface of the epithelial cells (pneumocyte) lining the lung. Sexual reproduction by trophozoites also occurs, first producing a precyst and then the cyst containing spores or intracystic bodies.

Laboratory diagnosis

Traditionally, diagnosis was made by finding the cyst or trophozoite in tissue obtained through open lung biopsy. Specimens now used include bronchoalveolar lavage (BAL) fluid, transbronchial biopsy specimens, tracheal aspirate, pleural fluid, and induced sputum. Sputum, however, is the least productive specimen. Lavage and sputum specimens are often prepared using a cytocentrifuge (Fig. 27.63).

Histologic stains, such as Giemsa and GMS stains, are used. With the methenamine silver stain, the cyst wall stains black. Cysts often have a punched-out ping-pong ball appearance. Fig. 27.64A shows the characteristic black-staining cyst of *Pneumocystis jirovecii* with methenamine silver stain. With the Giemsa stain, the organism appears round, and the cyst wall is barely visible. Intracystic bodies are seen around the interior of the organism. Fig. 27.64B shows the cyst stained with Giemsa stain. The cyst wall does not pick up the stain, but the nuclei of all forms stain pink, and the intracystic bodies can be demonstrated as a circular arrangement within the cyst.

Calcofluor white can be used to screen specimens for *Pneumocystis* and other fungi. This stain detects any

Fig. 27.63 Bronchoalveolar lavage, cytocentrifuge preparation, Gram stain, light microscopy, high power view. Purulence, none. Local materials, moderate. organism that contains chitin in its cell wall. Fungi, yeasts, and *Pneumocystis* will fluoresce with a blue-white color when stained and viewed microscopically with ultraviolet light (Fig. 27.65). Immunofluorescent monoclonal antibody stains are commercially available and are widely used.

Laboratory diagnosis of fungi

Safety issues

Because of the additional hazard of airborne conidia, a class 2 biological safety cabinet should be used to reduce exposure of personnel to fungal elements. Specimen processing and plating must be performed in a properly maintained and operating biological safety cabinet. The use of an enclosed electric incinerator is recommended to eliminate the hazards of open gas flames and to contain aerosolized particles emitted when loops or needles are incinerated. The cabinet should be checked daily to see that none of the air flow inlets or outlets is blocked by supplies, incinerators, or waste-disposal containers.

Use of Petri dishes in the mycology laboratory is hazardous; screw-top tubes (slants) are recommended instead for filamentous fungi. The chance for the release of airborne conidia is less likely with tubed media. Screw-capped tubes also tend to reduce dehydration of media and are more easily handled and stored compared with Petri dishes. However, Petri dishes have a larger surface area for colony isolation and are easier to manipulate when making preparations for microscopic examination. The edges of Petri dishes can be sealed with Parafilm or tape to reduce the risk of releasing airborne conidia.

Specimen collection, handling, and transport

Collection of appropriate specimens is the primary criterion for accurate diagnosis of mycotic infections. All specimens for mycology should be transported and processed as soon as possible. Because many pathogenic fungi grow

slowly, any delay in processing compromises specimen quality and decreases the probability of isolating the causative agent as a result of overgrowth by contaminants. In addition, all laboratories should maintain a protocol for the rejection of unsatisfactory or improperly labeled specimens.

Although almost any tissue or body fluid can be submitted for fungal culture, the most common specimens are respiratory secretions, hair, skin, nails, tissue, blood, bone marrow, and CSF. Table 27.8 presents the predominant culture sites for recovery of the causative agents of fungal diseases. Fig. 27.66 presents a schematic guideline to assist in making a diagnosis of a mycosis.

Hair, skin, or nails submitted for dermatophyte culture are generally contaminated with bacteria, rapidly growing fungi, or both. With these types of specimens, primary isolation medium should contain antimicrobial agents. The following procedures are recommended for collecting and processing clinical samples submitted for fungal studies.

Hair

The Wood lamp emits ultraviolet light of wavelength greater than 365nm and can be useful in identifying infected hairs. Hairs infected with fungi such as *M. audouinii* fluoresce when light from the Wood lamp is focused on the scalp. Sterile forceps should be used to pull affected hair. A less useful method involves cutting the hairs close to the scalp with sterile scissors. Hairs are placed directly into a sterile Petri dish. A few pieces of hair are inoculated onto fungal medium and incubated at 22° to 30°C.

Skin

Skin must be cleaned with 70% isopropyl alcohol before sampling. Skin samples are scraped from the outer edge of a surface lesion. A KOH wet mount is prepared with some of the scrapings; the KOH breaks down tissue, making it easier to view fungal hyphae. The remaining material is inoculated directly onto the agar.

Nails

Nails are cleaned with 70% isopropyl alcohol before the surface is scraped. Nail specimens may be submitted as scrapings or cuttings and occasionally as a complete nail. Deeper scrapings are necessary to prepare a KOH preparation and inoculate media. Sterile scissors are used to cut complete nails into small thin strips, which are used to inoculate media.

Blood and bone marrow

Blood from septicemic patients can harbor known pathogenic and opportunistic fungi, the most common being *Candida* spp. The lysis centrifugation system, the Isolator tube (Wampole Laboratories, Cranbury, NJ), is a method for the recovery of molds and dimorphic fungi. However, this method has a high contamination rate. The lysis of white blood cells (WBCs) and red blood cells releases microorganisms, which are then concentrated into sediment during centrifugation. The sediment is inoculated onto solid culture media. A biphasic system (broth and agar),

Fig. 27.65 Bronchoalveolar lavage, cytocentrifuge preparation, calcofluor white stain, fluorescence microscopy. Fluorescent cysts with coiled bodies. Morphology consistent with *P. jirovecii* ($\times 1000$).

Table 27.8 Predominant culture sites for recovery of causative agents^a

Infection	Respiratory	Blood	Bone marrow	Tissue	Skin	Mucus	Bone

Phaeohyphomycosis				+	+		

^aOrganisms may be recovered from multiple sites in disseminated infections.Fig. 27.66 Guideline for the identification of fungal isolates. *KOH*, Potassium hydroxide; *LPCB*, lactophenol cotton blue.

such as the Septi-Chek (BD Diagnostic Systems, Sparks, MD), can also be used. Automated and continuous monitoring blood culture systems have media designed for the recovery of fungi. As with bacteriology, blood volume and blood-to-broth ratio are important for optimal recovery of fungi. Studies indicate 20 to 30 mL of blood from adults divided among two bottles and a dilution of 5- to 10-fold is ideal. Heparinized bone marrow specimens should be plated directly onto media at the bedside; use of blood culture bottles is not recommended.

Cerebrospinal fluid

CSF and other sterile body fluids should be concentrated by centrifugation before inoculation. Part of the concentrate is used for India ink preparation or other assays for *Cryptococcus* (e.g., latex agglutination assay, EIA or lateral flow assay, as described later), and the remainder is inoculated onto media. If more than 5 mL is submitted, the CSF may be filtered through a membrane filter and portions of the filter placed on media. Use of media with antimicrobial agents should not be needed because CSF is normally sterile.

Abscess fluid, wound exudates, and tissue

Using a dissecting microscope, abscess fluid and exudate from wounds can be examined for the presence of granules. If no granules are present, the material may be plated directly onto the media. Tissue should be gently minced before inoculation. Grinding of tissue has been recommended, but this process might destroy fragile fungal elements, particularly if a mucormycete is present. Although grinding of tissue might be necessary for KOH and calcofluor white preparations, it should not be done unless sufficient tissue is present for mincing and grinding. When large sections of tissue are submitted, suspicious areas, such as purulent or discolored sections, are selected for mincing and grinding before subsequent culture.

Respiratory specimens

Because many fungal infections have a primary focus in the lungs, lower respiratory tract secretions (e.g., sputum, trans-tracheal aspirates) and lavage fluids (e.g., BAL) are commonly submitted. Patients should obtain sputa from a deep cough shortly after arising in the morning. If the patient cannot produce sputum, a nebulizer may be used to induce sputum. All sputum specimens should be collected in a sterile, screw-top container.

If the material is not too viscous, the specimens can be inoculated onto media with a sterile pipette. With viscous materials, such as a thick tracheal aspirate, a synthetic swab (e.g., Dacron) may be used to inoculate the material onto the media, or preferably the specimen can be digested with the mucolytic agent *N*-acetyl-L-cysteine and concentrated before inoculation. In addition to nonselective media, a medium with antimicrobial agents should be used to prevent bacterial overgrowth. A KOH preparation should also be made. Oropharyngeal candidiasis is easily diagnosed with direct smear and culture. Nasal sinus specimens obtained surgically can be plated directly to media containing antimicrobial agents except for cycloheximide, which can inhibit some fungi.

Urogenital and fecal specimens

Laboratory scientists often receive urine, feces, and vaginal secretions as specimens for bacteriologic culture; on occasion, these specimens grow a yeast that requires identification. Urine submitted specifically for fungal culture should be centrifuged and the sediment used to make smears for microscopic examination and to inoculate media. Quantification of yeast, as performed for bacteria, is not useful, and 24-hour specimens are unacceptable. A first-morning voided urine specimen is preferred.

Direct microscopic examination of specimens

Direct examination of clinical material for fungal elements serves several purposes. First, it helps provide a rapid report to the primary care provider, which may result in the early initiation of treatment. Second, in some cases, specific morphologic characteristics provide a clue to the genus of the organism. In turn, any special media indicated for species identification can be inoculated immediately. Third, direct examination might provide evidence of infection despite negative culture results. Such a situation can occur with specimens from patients who are receiving antifungal therapy, which may inhibit growth in vitro even though the infection can still be present in the patient.

Although Gram-stained smears of clinical samples examined in the routine microbiology laboratory often give the first evidence of infections with bacteria and yeasts, other direct stains give more specific information about mold infections. The types of direct examination used in identification of fungal infections include wet preparations, such as KOH, India ink, and calcofluor white stain. Histologic stains for tissue may also be useful.

KOH preparation

A 10% to 20% solution of KOH is useful for detecting fungal elements embedded within skin, hair, nails, and tissue (Fig. 27.67). In this procedure, a drop of the KOH preparation is added to a slide. Nail scrapings, hair, skin scales, or thin slices of tissue are added to the drop, and a coverslip is placed

Fig. 27.67 Skin scales, scrapings, potassium hydroxide wet preparation, light microscopy ($\times 400$). Hyphae present, septate, thin. Morphology suggests dermatophyte.

on top. The slide is then gently heated and then allowed to cool for approximately 15 minutes. The KOH and heat break down the keratin and skin layers, revealing more clearly fungi present in the specimen. Interpreting KOH slides remains difficult, and fungal elements can still evade detection.

Modifications of the KOH test can provide easier and more reliable results. These preparations incorporate dimethyl sulfoxide (DMSO) and a stain into the KOH solution. The DMSO facilitates more rapid breakdown of cellular debris without requiring heat, while the stain is taken up by fungal elements, making them readily visible on microscopic examination of the slide preparation.

Potassium hydroxide with calcofluor white

A drop of calcofluor white can be added to the KOH preparation before adding a coverslip. Calcofluor white binds to polysaccharides present in the chitin of the fungus or to cellulose. Fungal elements fluoresce apple green or blue-white, depending on the combination of filters used on the microscope; therefore any element with a polysaccharide skeleton fluoresces (Figs. 27.68 to 27.70). Because calcofluor white stains other structures, the actual fungal structure must be seen before a positive preparation is reported (Fig. 27.71). Care must also be taken when using this process because much variability exists among manufacturers and even in different lots of the stain prepared by the same manufacturer.

India ink

India ink or nigrosin preparations can be used to examine CSF for the presence of the encapsulated yeast *Cryptococcus*. A drop of India ink is mixed with a drop of sediment from a centrifuged CSF specimen, and the preparation is examined on high magnification ($\times 400$). With this negative stain, budding yeast cells surrounded by a large clear area against a black background are presumptive evidence of *Cryptococcus* (see Fig. 27.62). WBCs and other artifacts can resemble encapsulated organisms; therefore careful examination is necessary. Many laboratories, however, now use a cryptococcal antigen assay (see the “Cryptococcal Antigen” section later in this chapter) in place of the India ink examination.

Fig. 27.68 Bronchoalveolar lavage, cytocentrifuge preparation, calcofluor white stain, fluorescence microscopy ($\times 1000$). Fluorescent yeast, small, with capsules. Morphology suggests *Cryptococcus neoformans*. Impression: cryptococcosis.

Fig. 27.69 Soft tissue abscess, smear, calcofluor white stain, fluorescence microscopy ($\times 1000$). Fungal hyphae, septate, branched chlamydospores. Impression: mycosis. These hyphae were not clearly visible on the Gram stain smear, but they stain brightly here. A dermatophyte was isolated in culture.

Fig. 27.70 Skin scales from scrapings, calcofluor white stain, fluorescence microscopy ($\times 1000$). Hyphae, thin. Morphology suggests dermatophyte. Impression: dermatophytosis.

Fig. 27.71 Expectorated sputum, smear, calcofluor white stain, fluorescence microscopy ($\times 400$). Eosinophils. These cells are other structures that stain with calcofluor white. The granules from ruptured eosinophils stain brightly and should not be interpreted as remnants of fungi or parasites.

Fig. 27.72 Bone marrow stained with Giemsa stain showing the yeast phase of *Histoplasma capsulatum* (×1000).

The performance of these assays has improved over the years, and they are now recommended over the India ink preparations in screening CSF for *Cryptococcus* spp.

Tissue stains

Common tissue stains used in the histology department for detection of fungal elements include the periodic acid–Schiff (PAS), GMS, hematoxylin and eosin (H&E), Giemsa, and Fontana-Masson stains. Giemsa stain is used primarily to detect *Histoplasma* in blood or bone marrow (Fig. 27.72). PAS stain attaches to polysaccharides in the fungal wall and stains fungi pink. The Fontana-Masson method stains melanin in the cell wall and identifies the presence of phaeoid fungi. Table 27.9 lists the characteristic fungal reactions seen with selected stains.

Case check 27.2

When hyphal elements are seen in tissue sections, the disease is frequently attributed to *Aspergillus* spp. Although *Aspergillus* is the most common mold causing disease in the immunocompromised patient, dozens of other fungi, such as *Fusarium* in the Case in Point, give the same appearance. To document infection, the mold must be seen in tissue and grown in culture. When hyphae are not seen in tissue, the positive culture may be caused by a contaminant, and conversely, when hyphae are seen in tissue but not grown in culture, the causative agent cannot be determined.

Isolation methods

Culture media

In general, fungi do not share the broad range of nutritional and environmental needs that characterize bacteria, so relatively few types of standard media are needed for primary isolation. These include Sabouraud dextrose agar, Sabouraud dextrose agar with antimicrobial agents, potato dextrose agar or potato flakes agar, and BHI agar enriched with blood and antimicrobial agents. Gentamicin or chloramphenicol and cycloheximide are the antimicrobials usually included with fungal media. Gentamicin and chloramphenicol inhibit bacterial growth, whereas cycloheximide inhibits bacteria and many of the environmental fungi typically considered contaminants.

Table 27.9 Staining characteristics of fungi

Stain	Color of fungal element	Background color
Periodic acid–Schiff	Magenta	Pink or green
Grocott–Gomori methenamine silver	Black	Green
Giemsa	Purple-to-blue yeast with clear halo (capsule)	Pink to purple
India ink	Yeast with clear halo (capsule)	Black
KOH	Refractile	Clear
KOH–calcofluor white	Fluorescent	Dark
Fontana-Masson	Brown	Pink to purple

KOH, Potassium hydroxide.

The pH of the Emmons modification of Sabouraud dextrose agar is close to neutral and is a more efficient medium for primary isolation compared with the original formulation. Table 27.10 shows the expected growth results with some of the standard fungal media. Selective chromogenic agars, such as CHROMagar *Candida* (CHROMagar, Paris, France) and CHROMID *Candida* (bioMérieux, Durham, NC), provide a rapid preliminary identification.

Fungal media can be poured into Petri dishes or large test tubes to make slants. Petri dishes have the advantage of a larger surface area but are more prone to dehydration because of the prolonged incubation necessary for the recovery of some fungi. Petri dishes must be poured thicker than a standard medium for bacterial growth. The plates can be sealed with tape or Parafilm or sealed in semi-permeable bags to minimize dehydration and prevent the spread of fungal spores. Several examples of semi-permeable shrink seal bands are commercially available as well. Tubed media have the advantage of being safer to handle and less susceptible to drying. Fungal plates and tubes should be opened only in a biological safety cabinet.

Incubation

Most laboratories routinely incubate fungal cultures at room temperature or at 30°C. Fungi grow optimally at these temperatures, whereas bacteria have a slower growth rate. If the causative agent suspected is a dimorphic fungus, cultures should also be incubated at 35°C. Cultures are generally maintained for 4 to 6 weeks and should be examined twice weekly for growth. Mucorales, such as *Mucor* and *Rhizopus* spp., grow rapidly and may fill the tube or Petri dish with aerial mycelium within a few days, whereas more slowly growing organisms, such as *Fonsecaea* or *Phialophora* spp., might require 2 weeks or longer before growth is seen.

Information that should be recorded about an isolate includes the number of days until the first visible growth and the number of days required to see fruiting structures, whether mold or yeast forms are recovered, the media on which the fungus is isolated, the temperature at which growth occurs, and the morphology of the colonies.

Table 27.10 Summary of primary fungal culture media

Medium	Expected growth results
Incubated at 22°C	
SDA	Initial isolation of pathogens and saprobes Dimorphic fungi may exhibit their mycelial phase
SDA with antimicrobials ^a	Saprobes generally inhibited on this medium Dermatophytes and most of the fungi considered primary pathogens grow
BHI agar	Initial isolation of pathogens and saprobes
BHI agar with antimicrobials	Recovery of pathogenic fungi Dermatophytes not usually recovered
Inhibitory mold agar ^b	Initial isolation of pathogens except dermatophytes
SDA with chloramphenicol and cycloheximide ^c	Primary recovery of dermatophytes
At 37°C	
SDA	The yeast form of dimorphic fungi, and other organisms grow Dermatophytes grow poorly
BHI agar with blood	Yeasts, such as <i>Cryptococcus</i> , grow well The yeast form of <i>Histoplasma</i> takes up some of the heme pigment in the medium and becomes light tan, with a grainy, wrinkled texture

BHI, Brain-heart infusion; *SDA*, Sabouraud dextrose agar (4% glucose) or Emmons' modification with 2% glucose.
^aThe antimicrobial agents generally used are cycloheximide and chloramphenicol.
^bUsually contains chloramphenicol and is used for cultivation of cyclohexamide sensitive fungi (e.g., *Cryptococcus* spp. and *Candida* spp.). Yeast extract and glucose provide nutrients.
^cSeveral commercial formulations are available (e.g., Mycobiotic agar [Remel, Lenexa, KS] and Mycosel [BD Diagnostic Systems, Sparks, MD]).

Fungi identification

Although the number of fungal species described exceeds 100,000, the number known to cause human disease is a small fraction of this number, and although the number of species that are routinely seen causing infection is quite low, new species are continually being implicated. Most diseases are caused by a handful of species, making identification, at least to the genus level, fairly easy. The traditional starting place is to decide whether the isolate is a yeast or a mold. However, molds do not always produce structures that will facilitate identification. Often, cultures from clinical samples are sterile (hyphae only) or atypical.

None of the following tests alone is sufficient for proper identification, but when used together, accurate identification is often accomplished easily. Molecular and proteomic tests, whether culture based (DNA hybridization using probes, DNA sequencing and MALDI-TOF mass spectrometry) or PCR based, when used with these test procedures, enable the laboratory scientist to identify the most commonly encountered fungal isolates.

Macroscopic examination of cultures

Once an organism has grown, colonies must be examined for macroscopic characteristics. Gross morphologic traits, such as

color, texture, and growth rate, are initial observations that should be made. Pigment on the reverse side of the colony or in the aerial mycelium can be noted but is not always helpful, especially with the phaeoid fungi.

Microscopic examination

The most common procedure for microscopic examination is direct mounting of the fungal isolate. This is achieved by preparing a tease mount or cellophane tape mount. Many fungi routinely recovered can be identified by either of these two methods. Because of the risk of airborne conidia, these slides must be prepared in a biological safety cabinet. When fungi are atypical or an uncommon species is recovered, a slide culture should be prepared. Tease and tape mounts typically disturb conidia, preventing viewing of how they are formed, whereas slide cultures provide a more intact specimen. Fruiting structures, as well as conidial arrangement, are better observed by this method. The following microscopic characteristics should be observed:

- Septate versus sparsely septate or aseptate hyphae
- Hyaline or phaeoid hyphae
- Reproductive (fruiting) structures
- The types, size, shape, and arrangement of conidia/ascospores

Tease mount

For the tease mount, teasing needles or sterile applicator sticks are used to remove a portion of the mycelium from the middle third of the colony. The mycelia are placed in a drop of lactophenol cotton blue (LPCB) on a slide and gently teased apart. A modification of this procedure is more practical and permits retention of more of the fruiting structure. The mycelia are placed into a drop of LPCB on a slide but not teased apart, a coverslip is added, and the slide is examined microscopically at low and high magnifications.

LPCB is used to fix and stain tease or tape mounts from cultures. The combination of lactic acid, phenol, and the dye kills, preserves, and stains the organism. The hyphae take up the LPCB, but the stain does not work well with the phaeoid fungi because they retain their dark color. The major disadvantage of this procedure is the disruption of conidia during the teasing process.

Cellophane tape preparation

Cellophane tape preparations involve gently touching the surface of the colony with a piece of clear tape, sticky side down, and then removing it. The tape should not be pressed into the colony but should just gently touch the surface. Frosted tape does not work because the fungi are not visible through this type of tape. The tape is placed onto a drop of LPCB on a slide and examined. An advantage of this procedure is that the conidial arrangement is retained. Major disadvantages are the potential for contamination of the colony and the temporary nature of this preparation. Tape preparations should be read within 30 minutes and then discarded. A coverslip is not needed if the cellophane tape technique is used because the tape serves as a coverslip.

Slide culture

Slide cultures are useful for demonstrating the natural morphology of fungal structures and for encouraging conidiation

Fig. 27.73 A positive hair perforation test result shows penetration of the fungal agent in the hair shaft (arrow). This is the typical reaction by *Trichophyton mentagrophytes*, whereas *Trichophyton rubrum* causes only surface erosion of hair shaft (unstained, $\times 1000$).

in some poorly fruiting fungi. The slide culture can be preserved for a prolonged period, making those of known isolates useful for future comparison against isolates awaiting identification. Several methods have been devised for constructing slide cultures (see [Appendix D](#) on Evolve).

Miscellaneous tests for the identification of molds

Hair perforation test

In the hair perforation test, sterile 5- to 10-mm hair fragments are floated on sterile water supplemented with a few drops of sterile 10% yeast extract. Conidia or hyphae from the dermatophyte in question are inoculated onto the water surface. Hair shafts are removed and microscopically examined in LPCB at weekly intervals for up to 1 month. *T. rubrum* usually causes only surface erosion of hair shafts in this test, whereas *T. mentagrophytes* typically forms perpendicular penetration or wedge-shaped pegs in the hair shafts ([Fig. 27.73](#)). This test may be used to distinguish penetration-capable *M. canis* from *M. equinum*, which does not penetrate hair.

Urease test

Another test used to help differentiate *T. mentagrophytes* from *T. rubrum* is the 5-day urease test. Tubes of Christensen urea agar are very lightly inoculated with the dermatophyte and held for 5 days at room temperature. Most isolates of *T. mentagrophytes* demonstrate urease production, resulting in a color change of the medium from peach to bright fuchsia within that period, whereas most *T. rubrum* isolates are negative or require more than 5 days to give a positive reaction. This test is also useful for other molds and yeasts.

Thiamine requirement

Some dermatophytes cannot synthesize certain vitamins and therefore do not grow on vitamin-free media. Although several vitamin deficiencies are recognized in fungi, the test for thiamine requirement is perhaps the single most useful nutritional test for dermatophytes. Tubes of media with and without thiamine are inoculated with a tiny, medium-free portion of the colony and observed for growth after 10 to 14 days. Great care must be exercised to avoid transfer of culture medium with the inoculum because even

minuscule amounts of vitamin carried over can adequately supply the requirement and thereby result in a false growth reaction.

Trichophyton agars

Seven different *Trichophyton* agars, numbered 1 to 7, are used to determine the nutritional requirements of *Trichophyton* spp. Each of the media has different nutritional ingredients; after inoculation and incubation, growth is scored on a scale of 1 to 4. Based on the growth pattern, identification is made.

Growth on rice grains

Poorly sporulating isolates of *M. canis* can be difficult to differentiate from *M. audouinii*, a species that typically forms few conidia. Sterile, nonfortified rice is inoculated lightly with a portion of a colony. After 10 days of incubation at room temperature, the medium is observed for growth. *M. canis* and almost all other dermatophytes grow well and usually form many conidia, whereas *M. audouinii* does not grow but turns the rice grains brown.

Miscellaneous tests for the identification of yeasts

Germ tube production

The **germ tube** test is a relatively easy test to perform for the identification of yeasts. [Fig. 27.74](#) shows a schematic diagram of how the germ tube test can be used to presumptively identify yeast species. Both *C. albicans* and *C. dubliniensis* are identified with germ tube production ([Fig. 27.75](#)). The standard procedure (see [Appendix D](#) on Evolve) requires the use of serum or plasma, such as fetal bovine serum. Expired fresh-frozen plasma from the blood bank can also be used. However, this is not recommended because of the potential risk in the handling of bloodborne pathogens and because of concerns over reproducibility. Many other liquid media (e.g., BHI agar, trypticase soy broth, nutrient broth) have been used successfully as an alternative. The substrate is inoculated and then incubated at 35°C for 3 hours. Care must be taken not to incubate the test beyond 3 hours because other species are capable of forming germ tubes with extended incubation.

A presumptive identification of *C. albicans* or *C. dubliniensis* can be made when true germ tubes are present. This test provides only a presumptive identification because not all strains of *C. albicans* will be positive, and other species, in particular *C. tropicalis*, can yield false-positive results. True germ tubes lack constriction at their bases, where they attach to the mother cell. If a constriction is present at the base of a germ tube, the yeast is not either species. Such constricted germ tubes, called **pseudo-germ tubes**, are more characteristic of *C. tropicalis* ([Fig. 27.76](#)). *C. dubliniensis* is differentiated from *C. albicans* by its inability to grow at 42°C.

Carbohydrate assimilation

Sugar fermentation tests, although valuable, are time- and labor-intensive, making them impractical for use in the routine microbiology laboratory. Carbohydrate assimilation tests, however, can be readily performed as part of routine identification protocols. Assimilation tests identify which carbohydrates a yeast can use aerobically as a sole carbon source. Assimilation patterns can be determined from such methods

Fig. 27.74 Schematic diagram showing how the germ tube test can be used to presumptively identify yeasts.

Fig. 27.75 Germ tube production by *Candida albicans*. A true germ tube has no constriction at its base (unstained, $\times 1000$).

Fig. 27.76 *Candida tropicalis* shows constriction at the base of the germ tube, called a pseudo-germ tube (Nomarski optics, $\times 1250$).

as an automated identification system or various manual procedures and commercial kits. The individual laboratory should adopt the method that can be practically implemented into its particular working environment.

Several kits are available for identification of yeasts, including the API 20C yeast identification system (bioMérieux). In this assay, a series of freeze-dried sugars are placed into wells on a plastic strip. Yeast isolates are suspended in an agar basal medium, pipetted into the wells, and incubated at 30°C for 72 hours. As sugars are assimilated, the wells become turbid with growth. Wells remain clear when the sugar is not assimilated. A code is derived from the assimilation patterns and matched against a computerized database. Identifications are accompanied by a percentage, which indicates the probability that the identification is correct. Although this test is reliable, other auxiliary testing should accompany assimilation results before a final identification is made. Automated systems are also available for yeast identification. Many of these systems use enzyme and assimilation reactions to aid in yeast identification.

Chromogenic substrates

A number of media containing chromogenic substrates are available for the presumptive identification of yeasts. CHROMagar Candida presumptively identifies *C. albicans*, *C. tropicalis*, and about 10 other species. Identification is based on different colony colors, depending on the breakdown of chromogenic substrates by the different species. About 2% to 10% of *C. albicans* isolates are not identified on these media because they form white colonies.

Cornmeal agar

Yeast morphology on cornmeal agar is useful in determining identification of yeasts (see [Appendix D](#) on Evolve). Recognition of four different types of morphology is an important clue to identification: blastoconidia, chlamydoconidia, pseudohyphae, and arthroconidia.

Blastoconidia are the characteristic budding yeast forms usually seen on direct mounts of yeasts. *C. albicans* produces chlamydoconidia (chlamydospores) along with hyphae, as shown in [Fig. 27.77](#). A chlamydoconidium is a thick-walled conidium formed within or at the end of vegetative hyphae. Pseudohyphae ([Fig. 27.78](#)) are produced when the blastoconidia germinate to form a filamentous mat.

Fig. 27.77 *Candida albicans* on cornmeal agar showing typical chlamydoconidia (unstained, $\times 200$).

Fig. 27.78 Pseudohyphae occur when the blastoconidia germinate and form a filamentous mat (unstained, $\times 200$).

The cross-walls help determine whether the structures are true hyphae or pseudohyphae. Cross-walls of pseudohyphae are constricted and not true septations, whereas true hyphae remain parallel at cross-walls, with no indentation. Arthroconidia begin as true hyphae but break apart at the cross-walls with maturity. Rectangular fragments of hyphae should be accompanied by blastoconidia for an isolate to be considered a yeast.

Potassium nitrate assimilation

KNO_3 assimilation may provide useful information for separating the clinically significant yeasts. Use of the modified KNO_3 agar is a fairly rapid, easy, and accurate method to determine the ability of yeasts to use nitrate as the sole source of nitrogen. In a positive KNO_3 assimilation result, the medium turns blue, and in a negative result, the medium turns yellow. Control organisms that may be used include *Naganishia albida* (formerly *Cryptococcus albidus*) (positive) and *C. albicans* (negative).

Temperature studies

Temperature studies offer information for yeast identification. *Cryptococcus* spp. have weak growth at 35°C and no growth at 42°C . The optimal temperature for growth is about 25°C . Several *Candida* spp. have the ability to grow well at

temperatures as high as 45°C . *C. albicans* grows at 45°C , whereas *C. dubliniensis* does not. Similarly, *C. auris* is capable of growing at 40° to 42°C , whereas *C. haemulonii* and *C. duobushaemulonii*, two closely related species, are not.

Urease

Yeast isolates producing the enzyme urease can be detected easily with Christensen urea agar. The slants are inoculated and incubated at room temperature for 48 hours. Almost all clinically encountered *Candida* spp. are urease negative, whereas all *Cryptococcus* and *Rhodotorula* organisms are urease positive. Most strains of *Trichosporon* spp. are urease positive.

Diagnosis using clinical specimens and surrogate markers

(1,3)- β -D-Glucan

(1,3)- β -D-Glucan is an important component of the cell wall of various fungi, including pathogenic yeasts and molds. Major exceptions include *Cryptococcus* spp. and the Mucorales. Various assays are available, but only one, the Fungitell test (Associates of Cape Cod, Falmouth, MA), is available in the United States. This assay is a chromogenic test based on activation of the horseshoe crab coagulation cascade by (1,3)- β -D-glucan and uses amebocyte enzymes from *Limulus polyphemus*. Clinical studies have demonstrated the utility of this assay for the diagnosis of invasive fungal infections. However, various substances as well as some bacteria can lead to false-positive results. The cryptococci lack (1,3)- β -D-glucan, so they are negative. In addition, this is a panfungal assay, so a positive result does not provide information on the species that may be causing infection.

Galactomannan

The detection of galactomannan, a component of the *Aspergillus* cell wall, within plasma or BAL fluid is often used in the diagnosis of invasive infections caused by *Aspergillus* species. The detection of galactomannan is now part of the diagnostic criteria for probable invasive aspergillosis. One enzyme-linked immunosorbent assay (ELISA) method, the Platelia *Aspergillus* assay (Bio-Rad Laboratories, Hercules, CA), which uses a rat monoclonal antibody directed against an epitope in galactomannan in an ELISA format, was shown to be sensitive and specific in patients at high risk for invasive aspergillosis.

T2 magnetic resonance assay

A relatively new assay for the diagnosis of invasive candidiasis combines nuclear magnetic resonance spectroscopy with PCR to detect *Candida* cells directly in blood samples. One assay, the T2Candida assay (T2Biosystems, Lexington, MA), is approved by the U.S. Food and Drug Administration (FDA) and can detect five common *Candida* species: *C. albicans*, *C. glabrata*, *C. krusei*, *C. parapsilosis*, and *C. tropicalis*. This assay has excellent analytical sensitivity, being able to detect one to three colony-forming units of *Candida* per milliliter of blood. The results are rapidly available, usually within 4 hours in one study, compared with over 100 hours for traditional blood cultures, which is a major advantage. A research use only product is also available for *C. auris*.

Cryptococcal antigen

The detection of cryptococcal antigen, within either CSF or serum, has proven to be very useful in the diagnosis of cryptococcosis. Several available assays detect the glucuronoxylomannan component of the *Cryptococcus* antigen. These include latex agglutination assays, EIAs, and lateral flow assays. A lateral flow assay (IMMY cryptococcal lateral flow assay, Immuno-Mycologics, Norman, OK) is a rapid point-of-care dipstick test that uses a monoclonal antibody against the cryptococcal antigen. Because this assay is sensitive, is easy to perform, and does not require specialized equipment or refrigeration, the World Health Organization recommends that it be used in resource-limited settings for screening HIV-positive individuals for cryptococcosis.

Immunodiagnosis of fungal disease

Skin test reactivity to fungal antigens is sometimes used in the diagnosis of fungal allergies and infections. For example, *Aspergillus* spp. antigen extract is used for suspected allergic bronchopulmonary aspergillosis, atopic dermatitis, and allergic asthma. Skin testing for diagnosing fungal infection is valuable only if the patient has a history of a nonreactive skin test. A few antigen detection assays are commercially available for fungal pathogens including *Cryptococcus* spp. and *H. capsulatum*.

Although few are commercially available, assays to detect antibodies to fungi have also been used to help diagnose infection. Results depend on the antigen chosen and its quality. Cross-reactivity among related fungi has been reported. Double-immunodiffusion is probably the most commonly used method; however, interlaboratory discrepancies have been noted. One problem with serologic assays is the ubiquitous nature of many of the opportunistic fungi. Individuals can have detectable antibodies but not an active infection. It has also been shown that some individuals with *Aspergillus* spp. infections do not have detectable levels of antibody.

Antifungal susceptibility

Antifungal agents

Over the past few decades, fungal infections have steadily increased in incidence. This increase can be attributed to advances in medicine that have prolonged life expectancy, especially for those with chronic diseases. Advances in the area of transplantation medicine and chemotherapy, combined with immunosuppression from HIV infection, have created more patient populations susceptible to fungal infections.

Primary care providers have far fewer options for treating fungal infections compared with bacterial infections. Current options for treating fungal infection include drugs primarily from four classes: polyene, azole, echinocandin, and allylamine. For many years, the primary antifungal agent was amphotericin B, a polyene. This agent has a broad spectrum of activity in addition to fungicidal activity. Not only is this agent lethal to fungi, but it is also toxic

to humans. Patients treated with amphotericin B can experience many adverse side effects, including infusion-related reactions (fever, rigor, myalgia, and arthralgia) and renal impairment. Despite these problems, amphotericin B is frequently used for life-threatening fungal disease. Unfortunately, resistance to amphotericin B has been documented with *Scedosporium* spp., *L. prolificans*, *P. lilacinum*, *A. terreus*, and *Candida lusitanae* isolates.

The class that has provided the largest number of agents is the azoles. The most noteworthy compounds in this class include fluconazole, itraconazole, isavuconazole, posaconazole, and voriconazole. The azoles are important because they exhibit reasonable activity against fungi while causing fewer side effects. Fluconazole is the leading agent for treating yeast infections but has limited to no activity against molds. It is widely used by many practitioners to treat all types of infections, including vaginitis and thrush. Unfortunately, its overuse or misuse has resulted in the development of resistance, most notably with *C. glabrata*. Most *C. auris* isolates are also resistant to fluconazole, and *C. krusei* is considered intrinsically resistant. It is extremely important to determine the susceptibility pattern of a specific isolate before prescribing fluconazole for severe infections in patients who have been receiving long-term antifungal therapy.

The other azoles, itraconazole, isavuconazole, voriconazole, and posaconazole, are more frequently prescribed for treating mold infections. Itraconazole has been useful for treating aspergilli and phaeoid fungi infections. Isavuconazole and posaconazole have perhaps the broadest activity of the azoles against fungal species. Voriconazole has potent activity against the aspergilli, in addition to several emerging pathogens. Although prophylaxis with voriconazole is effective in decreasing infections by *Aspergillus* spp., it lacks activity against Mucorales.

The first agent to be released in the echinocandins group was caspofungin. This agent is lethal for yeast and, although effective against the aspergilli, is not generally lethal. This class targets cell wall synthesis, which makes it an attractive option for treating fungi that have developed resistance to other agents. Two other echinocandins are anidulafungin and micafungin. These two antifungals tend to have lower minimal inhibitory concentrations (MICs) compared with caspofungin. The CDC recommends an echinocandin for the treatment of invasive *C. auris* infections.

Two FDA-approved allylamines are terbinafine and naftifine. These compounds interfere with the synthesis of ergosterol, a principal sterol in the plasma membrane of many fungi. Terbinafine may be given orally or applied topically and is active against several groups of fungi, including the dermatophytes. Naftifine is used only topically.

Antifungal susceptibility testing

Until the past several years, many laboratories used methods that had been developed in-house to determine susceptibility patterns for the fungi. The Clinical and Laboratory Standards Institute (CLSI) in the United States has published four methods for antifungal susceptibility testing. These include M27 for yeast testing, M38 for mold testing, M44 for disk diffusion testing for yeasts, and M51 for disk diffusion testing for molds.

Although much debate exists regarding antifungal susceptibility testing, it is gaining popularity with more laboratories. The FDA has approved a microtiter method from TREK Diagnostic Systems (Thermo Fisher Scientific, Waltham, MA), a gradient diffusion method (Etest; bioMérieux), and MIC Test Strip (MTS; Liofilchem, Waltham, MA). Before these products were developed, only laboratories that could prepare their own reagents performed antifungal susceptibility testing.

The largest barrier to widespread antifungal testing is the lack of established breakpoints for most of the agents. Breakpoints are now species specific by drug, with results placing the organism categorically in the same manner as bacteria. These categories are S (susceptible), I (intermediate), and R (resistant) for the echinocandins. The azoles fluconazole and voriconazole are categorized as S, SDD (susceptible, dose dependent, fluconazole), I (for voriconazole), and R. The SDD category for fluconazole indicates isolates that may be considered susceptible when high-dose therapy, as opposed to standard therapy, is used.

Until breakpoints are established, the CLSI has provided epidemiologic cutoff values (ECVs). The ECV is an end point that can be used to evaluate a given MIC when clinical breakpoints are not available. The ECV does not indicate susceptible or resistant strains rather, wild-type and non-wild-type strains, where non-wild-type strains may harbor mechanisms of antifungal resistance. The health care provider will be able to review the activity of a drug against a specific strain to determine whether the MIC result is typical for that species or high. Those strains with an MIC above the ECV have potentially acquired mechanisms of resistance. Until other drugs are studied and breakpoints are established, the usefulness of antifungal susceptibility testing will most likely remain limited.

POINTS TO REMEMBER

- Yeasts typically reproduce by budding, whereas molds often reproduce by forming conidia/spores.
- A large array of fungi are capable of causing human infections.
- Fungi can be isolated from almost any type of clinical specimen.
- Fungal identification is based on a variety of characteristics, including macroscopic appearance, microscopic appearance, ability to grow at various temperatures, and biochemical reactions. Molecular and proteomic assays are now commonly used for fungal identification.
- Phaeoid (dematiaceous) fungi produce dark pigments.
- Dermatophytoses are caused by *Trichophyton*, *Microsporum*, and *Epidermophyton* species.
- The thermally dimorphic fungi *Blastomyces* spp., *Coccidioides immitis*, *Coccidioides posadasii*, *Histoplasma* spp., *Paracoccidioides* spp., *Sporothrix schenckii* species complex, and *Talaromyces marneffei* are often associated with systemic mycoses.
- Clinically important Mucorales include *Rhizopus*, *Mucor*, *Lichtheimia*, *Cunninghamella*, *Syncephalastrum*, *Apophysomyces*, and *Saksena*.
- *Geotrichum* is a mold that is often initially mistaken for a yeast.
- Saprobic fungi are most problematic in the immunocompromised host.
- *Candida albicans* is the most commonly isolated yeast and the one responsible for most human infections.
- *Pneumocystis jirovecii* is an important pathogen in patients with AIDS.
- Extreme care should be taken when working with dimorphic fungi in the laboratory. Cultures for all molds should be processed in a biological safety cabinet.
- Antifungal therapy is frequently ineffective when diagnosis is delayed.

LEARNING ASSESSMENT QUESTIONS

1. Which of the following organisms is the causative agent of tinea nigra?
 - a. *Microsporum canis*
 - b. *Trichosporon beigeli*
 - c. *Piedraia hortae*
 - d. *Hortaea werneckii*
2. Which of the following organisms is *not* a causative agent of chromoblastomycosis?
 - a. *Fonsecaea compacta*
 - b. *Talaromyces marneffei*
 - c. *Fonsecaea pedrosoi*
 - d. *Phialophora verrucosa*
3. A patient with very pale patches on his arms and legs is examined at his physician's office. His physician orders a fungal culture. The fungus shows a "spaghetti-and-meatball" appearance on direct smear. Which organism would you suspect?
 - a. *Microsporum canis*
 - b. *Malassezia furfur*
 - c. *Trichophyton rubrum*
 - d. *Epidermophyton floccosum*
4. Describe the characteristic microscopic appearance for each of the following dimorphic fungi when grown at 22° or 35°C.
 - a. *Blastomyces dermatitidis*
 - b. *Coccidioides immitis* and *C. posadasii*
 - c. *Histoplasma capsulatum*
 - d. *Sporothrix schenckii* species complex
5. What are the distinguishing microscopic characteristics for each of the following organisms?
 - a. *Nannizzia gypsea* (*Microsporum gypseum*)
 - b. *Microsporum canis*
 - c. *Trichophyton rubrum*
 - d. *Trichophyton mentagrophytes*
6. What are the expected results of the urease test and the hair perforation test for *T. rubrum* and *T. mentagrophytes*?
7. Which organism is one of the primary opportunistic infections in patients with acquired immunodeficiency syndrome?
 - a. *Pneumocystis jirovecii*
 - b. *Hortaea werneckii*
 - c. *Coccidioides immitis*
 - d. *Paracoccidioides brasiliensis*

8. What is the significance of isolating a saprobe from an infection in an immunocompromised patient?
9. How would you compare the macroscopic and microscopic morphology of the following saprobes: *Penicillium* spp., *Aspergillus fumigatus*, *Fusarium* spp., and *Curvularia* spp.?
10. What are the differences between chromoblastomycosis and eumycotic mycetoma?
11. What are the major differences between bacteria and fungi?
12. How are hyaline fungi different from phaeoid fungi?
13. Define *teleomorph*, *anamorph*, and *synanamorph*.
14. What are the expected results of the germ tube test for *Candida albicans*? What morphology would you likely see if you inoculated the colony onto cornmeal agar?
15. Large, one-celled, smooth to tuberculate macroconidia and smooth or echinulate microconidia are typical of the mycelial-phase growth of which of the following fungi?
 - a. *Blastomyces dermatitidis*
 - b. *Coccidioides immitis*
 - c. *Histoplasma capsulatum*
 - d. *Paracoccidioides brasiliensis*
16. Which of the following are the infectious structures of *Coccidioides immitis*?
 - a. Hyphae
 - b. Blastoconidia
 - c. Arthroconidia
 - d. Chlamydospores
17. Black-dot ringworm is an endothrix hair involvement caused by which of the following dermatophytes?
 - a. *Microsporum canis*
 - b. *Trichophyton tonsurans*
 - c. *Trichophyton mentagrophytes*
 - d. *Epidermophyton floccosum*
18. A subcutaneous fungal infection described as necrotic ulcers may follow direct inoculation of fungal spores into the skin. The causative agent when cultured at 37° C forms small, cigar-shaped yeasts and at room temperature, grows as a mold with delicate hyphae and rosette-like conidia. What is the name of this disease?
 - a. Blastomycosis
 - b. Chromomycosis
 - c. Sporotrichosis
 - d. Mycetoma
19. Most cases of pulmonary infections and invasive diseases caused by *Aspergillus* in humans result from which of the following organisms?
 - a. *Aspergillus fumigatus*
 - b. *Aspergillus flavus*
 - c. *Aspergillus niger*
 - d. *Aspergillus terreus*
20. A 10-year-old patient was admitted to the hospital with diabetic ketoacidosis. Three days later, he complained of nasal sinus blockage. Within 3 days, white fluffy mold grew from the sinus drainage and showed erect sporangioophores terminating in dark sporangia and sporangiospores. Brown rhizoids appeared at the base of the sporangioophores. Which of the following organisms would you suspect to identify?
 - a. *Alternaria*
 - b. *Mucor*
 - c. *Rhizopus*
 - d. *Curvularia*

Bibliography, 706

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. List the major considerations in the collection and handling of specimens for the identification of intestinal and blood and tissue parasites.
2. Describe protocols for sample collection, handling, and transport of specimens for blood and tissue parasites.
3. Describe the general procedures for performing the direct wet mount, fecal concentration, and permanently stained smears.
4. Determine the stages of parasites found during microscopic examination of fecal material with direct wet mount, fecal concentration, and permanently stained smears.
5. Compare the procedures and uses of thick and thin blood smears for the identification of blood parasites.

6. Justify performing a thick and thin blood smear for the identification of blood parasites.
7. Justify the use of molecular assays to detect parasites in clinical specimens.
8. Compare the general characteristics of the major phyla of human parasites.
9. Discriminate between pathogenic and nonpathogenic protozoa on the basis of morphologic features.
10. Justify reporting nonpathogenic intestinal parasites when they are identified in clinical specimens.
11. For the major human pathogens, describe the mechanism of pathogenesis, clinical symptoms, treatment, and prevention.
12. For each organism presented, describe the morphology; life cycle, including the infective and diagnostic stages; and usual procedure for identification.

KEY TERMS

Amastigote	Hexacanth embryo (oncosphere)
Appiqué forms	Intermediate hosts
Asexual reproduction	Karyosome
Axostyle	Kinetoplast
Blackwater fever	Maurer dots
Bradyzoites	Merozoites
Cercaria	Metacercaria
Chromatoidal bars	Microfilariae
Cyst	Miracidium
Cysticercus	Peripheral chromatin
Cytostome	Polyvinyl alcohol (PVA)
Definitive hosts	Primary amebic meningoencephalitis (PAM)
Erythrocytic phase	Proglottids
Exoerythrocytic phase	Rapid diagnostic tests (RDTs)
Filariform larvae	Rhabditiform larva
Gametes	Schizogony
Gametocytes	Schizont
Granulomatous amebic encephalitis (GAE)	Schüffner stippling

Scolex
Sexual reproduction
Sporoblast
Sporocysts
Sporogony
Sporozoites

Tachyzoites
Trophozoites
Trypomastigote
Undulating membrane
Vectors
Ziemann dots

Case in point

A 4-year-old male patient was brought to the public health clinic because of intermittent bouts of diarrhea lasting almost 4 weeks. The mother did not note any bright red blood in his stool. The child was pale, listless, and had a protuberant abdomen. He had several small erythematous vesicles on his feet. His mother said that he sometimes ate dirt and always had a good appetite. The family lived in a rural part of Georgia and had a well from which they obtained their drinking water. This part of the county had only recently been connected to the local city's sanitation system. The white blood cell (WBC) count was $10.2 \times 10^3/\mu\text{L}$ (reference range, 4.8×10^3 to $10.8 \times 10^3/\mu\text{L}$), and the differential showed 14% eosinophils (reference range, 0% to 4%). The hemoglobin level was 6.2 g/dL (reference range, 9 to 14 g/dL), and the reticulocyte count was 8% (reference range, 0.5% to 2%). The red blood cell (RBC) morphology was described as microcytic and hypochromic. The physician ordered a stool culture for bacterial pathogens and an ova and parasite (O & P) examination. The bacterial culture was negative for enteric pathogens, but the O & P examination revealed parasitic organisms and the presence of Charcot-Leyden crystals.

Issues to consider

After reading the patient's case history, consider:

- Significant features in the patient's history
- Intestinal parasites that should be considered part of the patient's differential diagnosis
- Additional laboratory tests that could aid in the diagnosis

Parasites are an important cause of human morbidity and death in many parts of the world. However, in the United States and other developed countries, they are seldom regarded as major causes of disease. Although parasites are often associated with gastrointestinal (GI) infection or, in the case of malaria, a blood infection, other parasites can live in organs and be transmitted via organ transplants. Some can invade the central nervous system (CNS). A few can cross the placenta and cause congenital infection. Health care professionals have become increasingly aware that parasites should be considered as possible causative agents of a patient's clinical condition. The factors that have led to this greater awareness include the rising number of immunocompromised patients susceptible to infections caused by known pathogens and opportunistic organisms, the increase in the number of people who travel to countries that have less than ideal sanitation and a large number of endemic parasites, and the growing population of immigrants from areas with endemic parasites. In addition, there is concern that ongoing climate change might affect the movement of insect vectors into new geographic areas, thus expanding the range of some diseases normally associated with tropical climates.

When a health care provider encounters a case of an infection that may be caused by a parasite, the patient's symptoms and clinical history, including travel history, are significant

data that must be gathered and shared with the laboratory scientist. The clinician and laboratory scientist should collaborate to make sure that the appropriate specimen is properly collected, handled, and examined. Parasitic infections can be difficult to diagnose, however, because patients often have nonspecific clinical symptoms that can be attributed to a number of disease agents. Knowledge of common pathogens and nonpathogens that exist in specific geographic regions and for a given body site is necessary to ensure proper identification and, if necessary, therapy.

Detection and identification of a parasite depend not only on the adequacy of the submitted specimen but also on the procedures established by the clinical laboratory, including the criteria for specimen collection, handling, and transport and for the laboratory methods used. Due to the low incidence of parasitic infections in the United States, many laboratories do not have extensive experience detecting parasites. This chapter discusses the major medically important parasites, their epidemiology and life cycle, and the clinical infections they cause. In addition, it presents the diagnostic features that characterize these agents. Readers are referred to parasitology references for detailed procedures, reagent preparation, and a comprehensive description of parasites that have been implicated in human disease.

General concepts in parasitology laboratory methods

Fecal specimens

Collection, handling, and transport

The collection and handling of a stool specimen before laboratory examination may influence whether organisms will be identified. The stool should be delivered to the laboratory as soon as possible after collection, or a portion should be placed immediately in a preservative. **Trophozoites, the motile and reproductive form of some amebae, or eggs of some helminths may disintegrate if not preserved or examined within a short time after collection.** Because many intestinal organisms are shed into the stool irregularly, a single stool specimen may be insufficient to detect an intestinal parasite. Studies have shown that only 58% to 72% of protozoa are detected with a single specimen. Traditionally, for optimal detection of intestinal parasites, a series of **three stool specimens collected a day or two apart, within a 10-day period,** has been recommended. This procedure of examining each specimen submitted is time-consuming and labor-intensive. Published articles suggest that in some circumstances, pooling of the three formalin-preserved specimens gives a parasite recovery rate comparable with that of the individual examination of formalin-preserved stools. Although this method saves time, there is a risk that if organisms are present in small numbers, they may be missed on microscopic examination of wet mounts because of a dilution effect (i.e., reduced sensitivity). Another cost-effective option includes examination of a second or third specimen only if the first test is negative and the patient remains symptomatic. Many laboratories establish an algorithm that considers the types of parasitology examinations routinely performed (e.g., antigen detection, nucleic acid

amplification testing [NAAT], fecal concentration, permanently stained smear, patient population, and specific criteria (e.g., travel, symptoms, immune status, inpatient or outpatient classification) to determine if a single specimen or multiple stool specimens should be examined.

It has been recommended that permanently stained smears be made and examined for each specimen individually. In addition, whether the patient is an inpatient or outpatient, the presence of symptoms should dictate whether three specimens are needed. For example, although inpatients frequently acquire healthcare-associated bacterial infections, it is highly unlikely that an inpatient would acquire a healthcare-associated parasitic infection. An immunoassay for *Giardia duodenalis* or *Cryptosporidium* may be requested on specimens from immunocompromised patients with diarrhea or children in daycare settings who are symptomatic in place of, or in addition to, the usual O & P procedure. Reflex testing often begins with an immunoassay or multiplex procedure for parasite antigens of the more common organisms, such as *Giardia*, and then a routine O & P examination is performed, if the results are negative, and the patient is symptomatic.

The collection container for feces should be clean, dry, sealed tightly, and waterproof (e.g., a plastic container with lid). Commercial systems that incorporate collection container and preservatives are also available. Stool specimens should never be collected from bedpans or toilet bowls; such practice might contaminate the specimen with urine or water, resulting in the destruction of trophozoites or introduction of free-living protozoa. As an alternative, the specimen could be collected on a clean piece of waxed paper or newspaper and transferred to the container. Another alternative is to use a disposable collection container that can be fitted under the toilet bowl rim. The specimen should be submitted as soon as possible after passage. The specimen should be properly labeled as discussed in Chapter 6.

Stool specimens for parasites should be collected before a barium enema, certain procedures using dyes, or the start of antimicrobial therapy. Antimicrobials can reduce the number of organisms present. If the patient has undergone a barium enema, stool examination should be delayed for 7 to 10 days because barium obscures organisms when specimens are examined microscopically, even after concentration procedures. If a purged specimen is to be collected, it is recommended that a saline or phosphosoda purgative be used because mineral oil droplets interfere with identification of parasites, especially protozoan cysts, an infective dormant form resistant to environmental stress. The second or third specimen after the purge is more likely to contain trophozoites that inhabit the cecum.

Preservation

Several methods are available for stool preservation if the specimen will not be delivered immediately to the laboratory. The preservative used is determined by the procedure to be performed on the fecal sample. Regardless of the preservative used, the ratio of three parts preservative to one part feces should be maintained for optimal fixation. Table 28.1 presents some of the more common preservatives and their appropriate use. The time that the stool was passed and the time it was placed in the fixative should be noted on the laboratory requisition and container. A commercially available two-vial system using modified polyvinyl alcohol (PVA), a resin polymer, in

Table 28.1 Preservatives commonly used for fecal samples

Preservative	Laboratory examination method
Modified polyvinyl alcohol	Permanently stained smear, DNA-PCR
10% formalin	Formalin–ethyl acetate concentration, direct wet mount, and most immunoassays
Sodium acetate–acetic acid–formalin	Permanently stained smears, concentration, and most immunoassays
Merthiolate–iodine–formalin	Concentration and direct wet mount
Single-vial systems (EcoFix, Parasafe, PROTO-FIX)	Concentration, direct wet mount, permanently stained smears, and most immunoassays

DNA, Deoxyribonucleic acid; PCR, polymerase chain reaction.

one vial and 10% formalin in the other vial is commonly used. The system comes with patient instructions and a self-sealing plastic bag for transport. The classic PVA fixative, which consists of mercuric chloride (for fixation) and PVA (to increase adhesion of the stool to the slide), was traditionally used when a permanently stained smear was to be made. Because of the toxicity of mercuric chloride, modifications that do not contain mercury have been developed. The modified PVA preservatives do not provide the same level of microscopic detail as the mercury-based formula, but they are safer acceptable alternatives. Schaudinn fixative also contains mercuric chloride. The formalin vial is used for direct wet mount and concentration procedures.

Alternative nontoxic fixatives, EcoFix (Meridian Bioscience, Cincinnati, OH), Parasafe (Scientific Device Laboratory, Des Plaines, IL), and PROTO-FIX (Alpha-Tec Systems, Vancouver, WA) are single-vial fixatives for wet mounts and permanently stained slides that do not use formaldehyde or mercury compounds. The specimen only needs to be added to one vial that can be used for wet mount, concentration, and permanently stained slides. Evaluation of stains made from stools preserved with these compounds has shown differing quality of the stained preparations. In some cases, the background quality was poor, and in others a less sharp morphology of the organism was observed. The fixative sodium acetate–acetic acid–formalin (SAF) is another alternative that can be used for the preservation of fecal specimens when concentration procedures and permanent stains will be used.

Macroscopic examination

The examination of an unpreserved stool specimen should include macroscopic (gross) and microscopic procedures. The initial laboratory procedure is the macroscopic examination. Laboratories that receive stool specimens already placed into preservative(s) are not able to perform a macroscopic examination. During gross examination, intact worms or proglottids (tapeworm segments) can be seen on the surface of the stool. Gross examination of the specimen also reveals the consistency (liquid, soft, formed) of the stool sample. Consistency may help determine the type of preservative to be used, indicate the forms of parasites expected to be present, or dictate the immediacy of examination. Fig. 28.1 shows the relationship between stool consistency and protozoan stage. Cysts (infective stage) are most likely to be found in formed stool

Fig. 28.1 Relationship of stool consistency to protozoan stage.

and sometimes in soft stool, whereas liquid stool will most likely contain the trophozoite stage.

During gross examination, the color of the stool specimen is noted. A normal stool sample usually appears brown. Stool that appears black may indicate **bleeding in the upper GI tract**, whereas the presence of fresh blood may indicate bleeding in the lower portion of the intestinal tract. Any portion of the stool that contains blood or blood-tinged mucus should be selected for wet mount preparations and added to preservative. A liquid stool specimen should be examined within 30 minutes of passage to detect the presence of motile trophozoites. A formed stool specimen should be examined within 2 to 3 hours of passage if held at room temperature; however, examination may be delayed up to 24 hours after passage if the specimen is placed at 4° C. The specimen should not be placed in a 37° C incubator, which increases the rate of disintegration of any organisms present and enhances overgrowth by bacteria. Following macroscopic examination, the specimen should be placed into the appropriate fixative(s) for concentration and preparation of permanently stained smear.

Microscopic examination

Several diagnostic methods can be used in the microscopic examination of a fecal specimen:

- Direct wet mount examination (iodine-stained and unstained) of fresh stool specimens
- Concentration procedures with wet mount examination of the concentrate
- Preparation of permanently stained smears

In general, concentration and permanent staining procedures should be performed on all specimens.

Wet mount preparations

The direct wet mount of **unpreserved fecal material is primarily used to detect the presence of motile protozoan trophozoites in a fresh liquid stool or from sigmoidoscopy material.**

A liquid stool specimen or purged specimen may contain motile protozoan trophozoites; hence, purged specimens should be examined immediately (within 30 minutes) after passage to ensure motility of the organisms. A portion should also be placed in a fixative so permanently stained smears for definitive identification can be made. Formed stools are unlikely to yield motile trophozoites, thus a direct wet mount

examination is not necessary. Direct wet mounts are not performed on specimens received in fixatives.

The wet mount procedure uses a glass slide on which a drop of physiologic saline (0.85%) has been placed at one end and a drop of iodine (Dobell and O'Connor iodine, D'Antoni iodine, or 1:5 dilution of Lugol solution) at the other end. A small amount (2 mg) of feces is added to each drop and mixed well. Each preparation should be covered with a No. 1, 22-mm square coverslip. The preparation should be thin enough so newsprint can be read through it and should not overflow beyond the edges of the coverslip. In unfixed stool specimens, the saline preparation is useful for the detection of helminth eggs or larvae, motile protozoa, and refractile protozoan cysts. Iodine emphasizes nuclear detail and glycogen masses but kills trophozoites. Wet mounts are also made from a fecal specimen following a concentration procedure. This detects protozoan cysts, helminth eggs, and helminth larvae.

Reading the wet mount involves thorough examination of each coverslipped preparation at low power, starting at one corner and following a systematic vertical or horizontal pattern until the entire preparation has been examined. A high-power objective is used to identify any suspicious structures. Oil immersion should not be used on a wet preparation unless the preparation has been sealed.

Concentration techniques

Concentration techniques are designed to concentrate the parasites present into a small volume of fluid and remove as much debris as possible. Fresh or stool specimens in an acceptable preservative may be used. The concentrate sediment may then be examined unstained or stained with iodine. Protozoan trophozoites do not survive the procedure. Protozoan cysts, helminth larvae, and helminth eggs, however, can be detected using this method.

Sedimentation and flotation methods, both of which are based on the difference in specific gravity between the parasites and concentrating solution, are used to concentrate parasites into a small volume for easier detection and increased sensitivity. In sedimentation methods, the organisms are concentrated in sediment at the bottom of the centrifuge tube. In flotation methods, the organisms are suspended at the top of a high-density fluid. Overall, sedimentation methods concentrate a greater diversity of organisms, including cysts, larvae, and eggs. The formalin-ethyl acetate sedimentation (FES) method was the standard sedimentation method. A number of manufacturers now market self-contained fecal

concentration kits that do not use the solvent ethyl acetate. Some kits incorporating collection and concentration in a single tube may not require centrifugation, making them useful in rural areas and developing countries. Although these kits offer easier disposability and a cleaner preparation because of the filtration method used, studies indicate that their use is more expensive than that of the traditional FES method.

The zinc sulfate method is the usual flotation procedure, although other methods such as zinc chloride are also available. While the flotation methods yield less fecal debris in the finished preparation compared with the FES method, the flotation liquids can cause operculated eggs to open or collapse. It also tends to distort protozoan cysts. When used, this procedure may miss infertile *Ascaris lumbricoides* eggs and *Schistosoma* spp. eggs. Because of their high density, these eggs sink to the bottom of the test tube. Most organisms tend to settle after about 30 minutes. Therefore the examination should be performed as soon as possible after the procedure has been completed to ensure optimal recovery of organisms.

Permanently stained smears

Permanently stained smear preparations of all stool specimens should be made to detect and identify protozoan trophozoites and cysts. The characteristics needed for identification of the protozoa, including nuclear detail, size, and internal structures, are visible in a well-made and properly stained smear. The permanent stains commonly used include iron hematoxylin and trichrome (Wheatley modification of the Gomori stain). The stain of choice in most laboratories is the trichrome stain because results are somewhat less dependent on the technique, and the procedure is less time-consuming. Although some laboratories prepare the stain in-house, manufacturers provide prepared stains and reagents for this procedure. Trichrome staining can be performed on a smear made from a fresh stool specimen fixed in Schaudinn fixative or from one that has been preserved in PVA. Specimens preserved in SAF do not stain well with trichrome and should be stained with iron hematoxylin.

To prepare a trichrome-stained smear of a fresh specimen, applicator sticks are used to smear a thin film of stool across a 1- by 3-inch slide. The smear is placed immediately in Schaudinn fixative; it must not be allowed to dry before fixation. For PVA-fixed specimens, several drops of specimen are placed on a paper towel to drain excess fluid. The material on the paper towel is collected to prepare the smear in the same way as for a fresh specimen. The specimen should be allowed to air-dry thoroughly before staining.

In a well-stained trichrome smear, the cytoplasm of protozoan cysts and trophozoites stains blue-green, although *Entamoeba coli* often stains purple. Nuclear peripheral chromatin (deoxyribonucleic acid [DNA] and proteins on the edge of the nucleus), karyosome (mass of chromatin in the nucleus), chromatoidal bars (dark-staining cytoplasmic inclusions of chromatin), and RBCs stain dark red to purple. Eggs and larvae stain red; however, they are often distorted or destroyed in the staining process. Background debris and yeasts stain green. With an iron hematoxylin stain, the parasites stain gray to black, nuclear material stains black, and background material stains light blue to gray. With either stain, poor fixation of fecal material results in poorly staining or nonstaining organisms. Several modifications of the trichrome staining procedure have been developed to allow the detection of a group of organisms known as the *microsporidia*.

All permanently stained smears should be examined by first scanning for thick and thin areas using lower-power magnification ($\times 10$ or $\times 40$ objective). Thin areas should be selected and examined under oil immersion ($\times 100$ objective) for identification of organisms. It should take approximately 10 to 15 minutes to adequately examine selected areas. Organisms that stain lightly and may be difficult to identify in either the cyst or the trophozoite stage include *Entamoeba hartmanni*, *Dientamoeba fragilis*, *Endolimax nana*, *Chilomastix mesnili*, and *Giardia duodenalis*.

Modified acid-fast stain

The Kinyoun modified acid-fast stain is used to detect oocysts of *Cryptosporidium* spp., *Cystoisospora belli* (formerly *Isospora belli*), and *Cyclospora cayetanensis*. With this procedure, the oocysts appear as magenta-stained organisms against a blue background.

Other specimens examined for intestinal and urogenital parasites

Cellophane tape preparation for pinworm

The life cycle of the pinworm *Enterobius vermicularis* includes migration of the female from the anus at night to lay eggs in the perianal area. Therefore a fecal specimen is not the optimal specimen for diagnosis of infection with this organism. Instead, the cellophane tape preparation is routinely used for detection of suspected pinworm infections. This procedure involves swabbing the person's perianal area with a tongue blade covered with cellophane tape (sticky side out). The collection should take place first thing in the morning before the individual uses the bathroom or has bathed. After the sample has been taken, the sticky side of the tape is placed on a microscope slide and scanned at low- and high-power magnification for the characteristically shaped eggs. Adaptations of this procedure using paddles with a sticky surface are commercially available.

Duodenal aspirates

Material obtained from duodenal aspirates or from the duodenal capsule Entero-Test (HDC, San Jose, CA) may be submitted in cases of suspected giardiasis or strongyloidiasis when clinical symptoms are suggestive of infection but repeated routine stool examination results are negative. In the Entero-Test, the patient swallows a gelatin capsule containing a weighted string. One end of the string is taped to the side of the patient's mouth; the weighted end is carried into the upper small intestine. After about 4 hours, the string is brought up, and part of the mucus adhering to the surface is stripped off and examined on a wet mount for motile trophozoites. The remainder of the specimen is placed in a fixative for a permanently stained smear. Eggs of *Fasciola hepatica* and *Clonorchis sinensis* as well as oocysts of *Cryptosporidium* and *C. belli* can also be recovered.

Sigmoidoscopy specimens

Scrapings or aspirates obtained by sigmoidoscopy may be used to diagnose amebiasis or cryptosporidiosis. These specimens are examined immediately for motile trophozoites, and a portion of the sample is placed in PVA fixative so

permanently stained smears can be prepared for examination. If cryptosporidiosis is suspected, a smear for staining with a modified acid-fast stain or by a fluorescent procedure should be prepared.

Urine, vaginal, and urethral specimens

Eggs of *Schistosoma haematobium* and *E. vermicularis* and trophozoites of *Trichomonas vaginalis* can be detected in urine sediment. *T. vaginalis* can also be detected in a wet mount of vaginal or urethral discharge. Envelope culture methods for *T. vaginalis*, such as the InPouch TV (Biomed Diagnostics, White City, OR), are also available. In this system, the specimen is added to the medium and incubated. Growth of the organism can be microscopically observed through the pouch within 3 days. Rapid antigen detection kits and molecular assays for *T. vaginalis* are also available.

Sputum

In cases of *Strongyloides stercoralis* hyperinfection, **filariiform larvae** may be seen in a direct wet mount of sputum and bronchoalveolar lavage and washings. Larval forms of other migrating helminths, such as *A. lumbricoides* and hookworm, can also be detected. Eggs of the lung fluke *Paragonimus westermani* can be identified in a wet mount. In addition, *Entamoeba histolytica*, *Cryptosporidium* oocysts, and microsporidia can be found in lower respiratory tract specimens. If the patient is suspected of having a pulmonary infection caused by these agents, the specimen should be examined as a permanently stained smear.

Examination of specimens for blood and tissue parasites

Blood smears

Depending on the blood parasite, whole blood or buffy coat preparations can be used. Examination of a whole blood smear stained with the Giemsa or Wright stain is the most common method of detecting *Plasmodium*, *Babesia*, *Trypanosoma*, and some species of microfilaria. Although motile organisms, such as *Trypanosoma* trypomastigotes and **microfilariae** (larval form of filarial worms), can be detected on a wet preparation of a fresh blood specimen under low- and high-power magnification, identification is made on the basis of characteristics seen on a permanently stained smear. Stained smears from buffy coats are helpful in finding *Leishmania* spp. and *Toxoplasma gondii* in the cytoplasm of mononuclear cells. The yeast form of the dimorphic fungus *Histoplasma capsulatum* can also be seen. Concentration methods using membrane filters can be used to detect *Trypanosoma* spp. or microfilariae, but these methods are rarely used in the clinical laboratory.

Collection and preparation

Blood taken directly from a finger stick is the ideal specimen for a malarial smear because it tends to give the best staining characteristics. Blood collected in ethylenediamine tetraacetic acid (EDTA) gives adequate staining if processed within 1 hour. Distortion of the organism may occur if the time to preparation of the slide is longer than 1 hour, and organisms may be

lost if the time exceeds 4 hours. For example, the **gametocytes** of *Plasmodium falciparum* may lose their characteristic banana shape and round up. With Giemsa stain, the cytoplasm of the parasite stains bluish, and the chromatin stains red to purple red. If malarial stippling is present, it appears as discrete pink-red dots. The Giemsa stain gives the best morphologic detail but is a time-consuming procedure. Wright stain has a shorter staining period, but the color intensity for the differentiation of parasites is not as good as that with Giemsa stain.

Identification procedure

For suspected cases of blood parasites, a thick film and a thin film should be made. Both preparations can be made on the same slide or on separate slides. Because the two preparations are treated differently before staining, however, use of two slides may be more convenient. The Giemsa stain provides the best staining of the organisms and should be used on thick and thin films. Thin smears must first be fixed in methanol before staining with the Giemsa stain. RBCs in the unfixed thick smear will lyse during the staining procedure. Unless the RBCs on the slide are first lysed in distilled water, Wright stain cannot be used for a thick film because the stain contains methanol, which will fix RBCs.

A thick film is best for the detection of parasites (high sensitivity) because of the larger volume of blood and the fact that organisms are concentrated in a relatively small area. The thick film is made by pooling several drops of blood on the slide and then spread into a circular area with a diameter approximately equal to 1.5 cm. A film that is too thick peels from the slide; thickness is optimal when newsprint is barely visible through the drop of blood before it dries. The blood should be allowed to dry for at least 6 hours before staining. It should not be fixed with methanol before staining; fixing prevents lysis of the RBCs. The Giemsa stain releases hemoglobin by lysing unfixed RBCs. Initial scanning of the stained smear at $\times 100$ magnification detects microfilariae. The thick smear is examined at $\times 1000$ magnification for the presence of malarial organisms. In the thick film, the RBCs are destroyed, so only WBCs, platelets, and parasites are visible. In a thick film, the organisms may be difficult to identify, and there is no way to compare the size of infected and noninfected erythrocytes. Therefore species identification should be made from a thin film because the characteristics of the parasite and the RBCs can be seen.

The thin film is made in the same way as that for a differential cell count. It should be fixed in methanol for 1 minute and air-dried before staining with Giemsa stain. The entire smear should be scanned at low-power ($\times 100$ magnification) for detection of large organisms such as microfilariae; then at least 100 oil immersion fields ($\times 1000$ magnification) must be examined for the presence of organisms such as *Trypanosoma* or intracellular organisms such as *Plasmodium* or *Babesia*. Because the RBCs are intact, the thin smear has a higher specificity compared with a thick smear. For a symptomatic patient, several blood smears from samples collected at approximately 6-hour intervals over 36 to 48 hours should be examined before a final negative diagnosis is made. *Parasitemia* (percentage of erythrocytes parasitized) can be calculated from the thin blood smear. It is recommended that a minimum of 500 RBCs be counted. The calculation is as follows:

$$\left(\frac{\text{Number of infected RBCs}}{\text{Total number of RBCs counted}} \right) \times 100 = \text{Percent infected RBCs}$$

Biopsy specimens

Biopsy specimens are typically examined using stained tissue sections processed in the histology section of a clinical laboratory. Tissues that might yield parasites include skin, muscle, cornea, intestine, liver, lung, and brain. Biopsy specimens are usually needed to diagnose infections with *Leishmania* spp. because the organisms are intracellular. Depending on the species present, the amastigote (obligate intracellular form) can be detected in tissues, such as skin, liver, spleen, and bone marrow. Cutaneous lesions should be sampled below the edges of the ulcer; surface samples do not yield infected cells. Biopsy of striated muscle may also be performed for the diagnosis of *Trichinella spiralis*. *T. gondii* can also be identified by examination of tissue and muscle biopsy specimens.

Cerebrospinal fluid

Viable organisms in suspected cases of amebic meningitis or sleeping sickness can occasionally be seen in a cerebrospinal fluid (CSF) specimen. The **trypomastigote**, an extracellular nonreplicating form, is readily visible because of the motion of the flagellum and undulating membrane. It requires a skillful microscopist, however, to discern amebic motility in a field of neutrophils. If amebic meningoencephalitis caused by *Naegleria fowleri* is suspected, CSF can be cultured. Nonnutrient agar is seeded with an *Escherichia coli* overlay, and the CSF sediment is inoculated onto the medium. The specimen is sealed and incubated at 35° C. The medium is microscopically examined daily for thin tracks made by the amebae as they feed on the bacteria.

Immunologic diagnosis

Parasites that invade tissue (e.g., *E. histolytica*, *Trypanosoma cruzi*, or *T. gondii*) are the primary organisms that stimulate antibody production. Serologic tests are sometimes useful if invasive methods cannot be used for identification. In most cases, however, tests for antibody serve only as epidemiologic markers, especially in endemic areas. Detection of immunoglobulin M (IgM) can be useful in identifying infection during the acute phase, but this class of antibody generally declines to nondetectable levels as the infection begins to resolve. Detection of immunoglobulin G (IgG) does not distinguish between a relatively recent infection and a past infection because this class of antibody can persist for years. In some cases, however, detection of antibody is useful—for example, a patient who lives in an area nonendemic for a parasite has recently traveled to an endemic area and now shows symptoms, but the organism has not been detected in a clinical specimen. A positive test for antibody would help confirm a diagnosis. Another disadvantage of antibody tests is that they can have many cross-reactions that limit their diagnostic usefulness. In addition, it is difficult to obtain quality parasite antigen. Many serologic tests are used by reference laboratories, such as the U.S. Centers for Disease Control and Prevention (CDC), and are not commercially available.

The parameters that should be considered in selecting a method to be used should therefore include not only cost but also diagnostic yield, patient population, relative incidence of the parasite in the area, and number of specimens to be processed. Classically, such methods as hemagglutination or complement fixation were used to detect antibodies to

parasitic organisms. Newer tests use fluorescent or enzyme immunoassay (EIA) techniques. Immunoassay tests for antibodies to *T. gondii* or *E. histolytica* (extraintestinal infections) are available for use in clinical laboratories.

Enzyme immunoassays

The major use of EIA has been to detect parasite antigens in clinical specimens. These tests, in contrast with antibody tests, provide information about current infection. Several EIAs are available to detect the presence of *Giardia duodenalis*, *Cryptosporidium* spp., *E. histolytica*, and *Entamoeba dispar*. The sensitivity and specificity of these tests to detect intestinal parasites is excellent compared to microscopic examination. Some can find more than one parasite in the specimen by detecting antigens of the organism in the stool using organism-specific antibodies immobilized on a membrane. Rapid EIA kits that can be used with fresh or preserved fecal specimens and kits using monoclonal antibody to detect *Giardia* and *Cryptosporidium* antigens are also available. Not all kits detecting *E. histolytica*, however, can differentiate between *E. histolytica* (pathogenic) and *E. dispar* (nonpathogenic). Antigen detection kits have replaced microscopic examinations in some hospital laboratories.

Another growing area of EIA application testing is field diagnosis of malaria. Although most of these tests are used in endemic areas, one has been approved by the U.S. Food and Drug Administration (FDA) for use in the United States. These tests are based on the principle of immunochromatographic antigen capture (see [Chapter 10](#)), and use whole blood to detect malarial proteins. The patient's blood is reacted with monoclonal antibody labeled with dye or gold particles. Some tests are relatively non-species specific and detect a protein, such as parasite lactate dehydrogenase or aldolase, that is common to all four human *Plasmodium* spp. Other tests may detect a species-specific protein, such as histidine-rich protein, which is associated with *P. falciparum*. Some tests detect both types of protein to provide a more complete picture of the infective agent.

Fluorescent antibody techniques

Direct fluorescent antibody (DFA) techniques using monoclonal antibodies have been developed to detect *Cryptosporidium* oocysts in fecal specimens. Fecal material is spread on a slide, reagent containing the antibody is added, and the specimen is examined under a fluorescent microscope for a characteristic apple-green structure. These methods are more expensive than the modified acid-fast procedure but demonstrate greater sensitivity, especially when only rare oocysts are present. A DFA combination reagent for *G. duodenalis* and *Cryptosporidium* antigens is also available. The monoclonal antibodies help avoid false-positive and false-negative results. Such procedures are useful in screening large numbers of specimens during epidemiologic studies. DFA assays have greater sensitivity and specificity compared with routine stains.

The quantitative buffy coat (QBC; Drucker Diagnostics, Port Matilda, PA) procedure uses the fluorescent dye acridine orange to stain nuclear material for detecting malarial organisms in blood. A microhematocrit tube is coated with the fluorescent dye. After centrifugation, the parasites can be viewed

in a small area at the top of the erythrocyte column. This method is more sensitive than a thick smear in demonstrating the presence of parasites, but a thin smear must still be made for definitive identification. However, the instrumentation required may not be available for use in all areas of the world.

Molecular methods

Molecular methods for parasite identification are rapidly being adopted by clinical laboratories. Methods can include classic and real-time polymerase chain reaction (PCR) assays. Molecular methods of detection exist that identify several organisms, including malarial parasites. Multiplex PCR panels are commercially available for GI pathogens that can detect a significant number of viruses and bacteria and a limited number of parasites (e.g., *Giardia duodenalis*, *E. histolytica*, *Cryptosporidium* spp., and in some cases *Cyclospora cayentanensis*). *Dientamoeba fragilis*, *Blastocystis* spp., and microsporidia do not yet have a rapid identification procedure. Several of the current molecular procedures are rapid and do not require specimen processing. Although these newer methods have eliminated the need for routine concentration for selected organisms, the downside is that if the test result is negative and the patient remains symptomatic, routine procedures then should be instituted.

Quality assurance in the parasitology laboratory

Quality assurance procedures in the parasitology laboratory are like those in other laboratory sections. An updated procedure manual, controls for staining procedures, and records of centrifuge calibration, ocular micrometer calibration, and refrigerator and incubator temperatures should be available. Reagents, solutions, and kits must be properly labeled. In addition, the parasitology laboratory should have the following:

- A reference book collection, including texts and atlases
- A set of digital images of common parasites; many are available online
- A set of clinical reference specimens, including permanently stained smears and formalin-preserved feces

The department should also be enrolled in an external proficiency testing program. An ongoing internal proficiency testing program can be used to enhance the identification skills of the clinical laboratory scientists, especially if a full-time parasitologist is not employed. It has been shown that approximately twice as many parasites are detected when a single laboratory scientist staffs the parasitology department compared with departments that rotate personnel through the department. One type of program might assess the reproducibility of results in the examination of fecal specimens. Preserved specimens that have been reported are reexamined as part of this program to see if the initial results (organism identification and quantification) are duplicated.

Size is an important diagnostic criterion for parasites, and use of a properly calibrated ocular micrometer ensures accurate measurement of organisms. The micrometer should be calibrated for each objective on the microscope. Calibration requires two parts: (1) the stage micrometer, a 0.1-mm line

that is ruled in 0.01-mm units, and (2) the ocular micrometer, which is ruled in 100 units but has no value assigned to the units. Values for each ocular unit can be calculated by using the stage micrometer according to the procedure found in [Appendix D](#) on Evolve.

Medically important parasitic agents

Historically, the human medically important eucaryotic parasites were classified as protozoan, helminth, and arthropod. More recently the microsporidia, which belong to the kingdom of fungi, were recognized as human pathogens. Due to their morphology and pathogenesis, the microsporidia are often considered with the parasites. Medically important parasites can be found in phyla representing single-celled organisms, such as the protozoa and sporozoa, and complex, multicelled organisms, such as the helminths (worms). [Table 28.2](#) lists the characteristics of the phyla in which most medically important human parasites are found; they are described in this chapter. The protozoan parasites are classified according to their motility organelles; the ameba move by pseudopodia, the flagellates move by flagella, and the ciliates move by cilia. The sporozoa are nonmotile. Helminths are classified according to their shape and include flatworms (flukes and tapeworms) and roundworms. Arthropods, such as *Pediculus humanus* (pediculosis) and *Sarcoptes scabiei* (scabies), cause human infestations. They can also sometimes be vectors for infectious pathogens. These agents are discussed in [Chapter 33](#).

Protozoa

The protozoan parasites include pathogens and nonpathogens (commensals). Some of the commensal organisms closely resemble the pathogens, so it is important for the laboratory scientist to be able to recognize and distinguish among them. This ensures that a patient will be given appropriate therapy when necessary and not be treated unnecessarily. Commensal parasites must be reported in the test results. It is important to recognize that the commensals are not considered normal biota, but their presence indicates that the patient has ingested fecally contaminated food or water. When a commensal is detected, it is important for the laboratory scientist to examine the specimen closely for the presence of a pathogen.

Intestinal amebae

In general, amebae present the most difficult challenge regarding identification. Their average size range is smaller than that of most other parasitic organisms, and they must be distinguished from artifacts and cells that appear in the clinical specimen. Species identification, whether in the cyst or in the trophozoite stage, often is based on the size, number of nuclei, nuclear structure, and presence of specific internal structures. In a direct wet preparation, the motility of the trophozoite may aid in presumptive identification. Overall, however, the permanently stained smear is the best preparation for identification of the amebae.

E. histolytica is recognized as a true pathogen, whereas *Blastocystis* spp. still have questionable status as a pathogen. Other amebae are considered nonpathogens. All of the amebic

Table 28.2 Characteristics of phyla of medically important parasites

Organisms	Characteristics
Phylum: Sarcomastigophora	
Subphylum: Sarcodina (ameba)	Single celled Move by pseudopodia Trophozoite and cyst stages Asexual reproduction
Subphylum: Mastigophora (flagellates)	Single celled Most move by action of flagella Trophozoite and cyst stages for intestinal organisms, except for <i>Dientamoeba fragilis</i> Asexual reproduction Some blood flagellates
Phylum: Ciliophora (ciliates)	Single celled Move by action of cilia Trophozoite and cyst stages Asexual reproduction
Phylum: Apicomplexa (sporozoa)	Single celled Usually inhabit tissue and blood cells Insects and other mammals are involved as part of life cycle May have both sexual and asexual life cycles
Phylum: Microsporidia	
	True eucaryotes with membrane bound nucleus Bacterium-like ribosomes No discernible mitochondria Belong to the kingdom of fungi
Phylum: Platyhelminthes (flatworms)	
Class: Trematoda (flukes)	Multicelled and bilaterally symmetric Most are hermaphroditic Egg, miracidium, cercaria, and adult are life cycle stages Fish, snails, and crabs are involved as intermediate hosts in life cycle
Class: Cestoda (tapeworms)	Multicelled, ribbonlike body Hermaphroditic Egg, larva, and adult worm are life cycle stages Mammals and insects are involved as intermediate hosts in life cycle
Phylum: Aschelminthes	
Class: Nematoda (roundworms)	Adults of both sexes Egg, larva, and adult worm are life cycle stages May have free-living form or may require intermediate host

organisms discussed here live in the large intestine. All amebae possess a trophozoite and cyst stage. *B. hominis* has additional morphologic stages. The trophozoite is the motile feeding stage that reproduces by binary fission. The cyst is an infective, environmentally resistant stage. Multiplication of nuclei in the cyst stage also serves a reproductive function.

Life cycle

The life cycle of amebae is relatively simple, with direct fecal-oral transmission in food or water via the cyst stage and no **intermediate hosts**. Humans ingest the infective cysts, which excyst in the intestinal tract, and the emerged trophozoites multiply by binary fission. Trophozoites colonize the cecal area. Fig. 28.2 illustrates a generalized life cycle for amebae and the extraintestinal phase of *E. histolytica*.

Treatment

Treatment is administered only for *E. histolytica* infections; treatment for nonpathogens is not indicated. Luminal amebicides, such as paromomycin, are given to carriers in nonendemic areas to prevent the invasive phase and reduce the risk of transmission. In endemic areas with a high risk of reinfection, treatment may not be indicated. Patients with invasive amebiasis are treated with systemic drugs, such as metronidazole and luminal amebicides. In cases of *Blastocystis* spp. infection, treatment may be indicated if the patient is symptomatic.

Entamoeba histolytica and related organisms

E. histolytica and *E. dispar* are morphologically identical organisms that differ in their effects on the host. *E. histolytica* is a recognized pathogen, while *E. dispar* is nonpathogenic. Recently, *E. moshkovskii* and *E. bangladeshi*, which are also morphologically identical to *E. histolytica*, have been identified as belonging to this complex. It is unclear if the latter two organisms are pathogenic; however, some studies indicate *E. bangladeshi* is an agent of diarrhea.

Historically, studies demonstrated that many people were infected with an organism identified as *E. histolytica*. However, only about 10% of these individuals developed clinical symptoms or invasive disease. It was thought that perhaps two strains of the organism existed, one pathogenic and one nonpathogenic. For many years, this hypothesis remained unproven because there was no way to differentiate the strains morphologically.

Clinical studies that took place after the emergence of human immunodeficiency virus (HIV) provided the impetus to explain the discrepancy. Studies using electrophoresis identified differing isoenzyme (zymodeme) patterns between organisms that caused clinical symptoms and those found in asymptomatic persons. The studies showed that most strains in asymptomatic cyst passers and in most men who have sex with men were nonpathogenic, whereas several strains from areas with high rates of endemic disease were pathogenic. Further immunologic and DNA probe studies supplied additional evidence, such as differences in epitopes of the galactose-binding lectin, differences in surface antigens, and differences in gene expression. On the basis of this evidence, the noninvasive organism, formerly referred to as *nonpathogenic E. histolytica*, was named *E. dispar*. The pathogenic organism continued to be referred to as *E. histolytica*. *E. moshkovskii* is morphologically identical to *E. histolytica* and *E. dispar* and

Fig. 28.2 Generalized life cycle of intestinal amoeba.

was thought to be a free-living organism. Subsequent studies identified it as a GI organism reported from humans in many countries. Its true significance is unknown, but initial evidence suggests that it is nonpathogenic.

The organisms are morphologically identical and must be distinguished on the basis of identification of surface antigens. However, the presence of ingested erythrocytes in the trophozoite stage will distinguish *E. histolytica* from the other species. *E. histolytica* is found worldwide, but especially in the tropics and subtropics. It is a major protozoan pathogen for humans, causing an estimated 500 million infections and 50 million cases of colitis and hepatic abscesses annually. It ranks third behind malaria and schistosomiasis as a cause of death resulting from a parasitic infection, accounting for an estimated 40,000 to 100,000 annual deaths. Due to misdiagnosis and under-reporting, the prevalence is thought to be much greater. Prevalence of infection differs according to socioeconomic levels and sanitary practices; infection is more common in developing countries. Travelers to those areas are at increased risk of acquiring infection. Other factors that may influence susceptibility include specific human leukocyte antigen (HLA) phenotypes and mutations in the hormone leptin. Although the primary mode of transmission is fecal-oral transmission, the organism has also been identified as a sexually transmitted agent among men who have sex with men. HIV infection does not appear to increase the risk of invasive disease.

Clinical infection

E. histolytica normally subsists on intestinal bacteria and partially digested food of the host. The pathogenicity of

E. histolytica is reflected, however, in its ability to cause invasive intestinal amebiasis and extraintestinal amebic infections. The organism adheres to the mucous layer and cells of the intestine using surface lectins with affinity for galactose and *N*-acetyl-galactosamine. It invades and disrupts the mucosal barrier, produces contact-dependent killing, and induces apoptosis of the intestinal cells. A protein known as *amoebapore* will create a channel in the cell that allows rapid influx of calcium, resulting in cell death. The organism lyses and phagocytizes the cell. Invasion of the deeper layers of the intestinal wall is mediated by cysteine proteases that destroy collagen and fibronectin. Evidence suggests that trophozoites also use trogocytosis (the process of ingesting pieces of living cells) to disrupt cell membranes.

The host secretes proinflammatory cytokines, leading to an acute inflammatory response and migration of neutrophils and macrophages into the tissue. The organism can also secrete chemoattractants for neutrophils. It kills these cells by contact-dependent lysis, and the subsequent release of lysozymes, superoxides, and collagenases from the neutrophil granules produces additional damage to the intestinal mucosa.

The host's innate and acquired immune responses come into play to prevent colonization. Mucin in the intestinal mucus competes for attachment to the lectin and protects epithelial cells from attack. The host may have intestinal immunoglobulin A (IgA) that helps prevent colonization and repeat infection, and antigen-specific T cells secrete cytokines that have direct cytotoxicity for the trophozoites. The trophozoite is, however, resistant to complement-mediated lysis.

E. histolytica infection presents in several ways: asymptomatic colonization, amebic dysentery (colitis), and extraintestinal amebiasis. In almost 90% of infections, the patients are asymptomatic. Individuals who are colonized but remain asymptomatic pose a great risk to others because they are cyst passers and therefore infective. In symptomatic individuals, clinical infection may appear in an acute or chronic form. Those with increased risk for severe disease include young individuals, older adults, malnourished individuals, and those receiving immunosuppression therapy. In acute infections, the patient may experience vague abdominal symptoms, such as tenderness and cramping, fever, and up to 20 diarrheic stools per day that contain trophozoites, blood, and mucus. Some stools contain Charcot-Leyden crystals, which are breakdown remnants of eosinophils; their presence in the stool is suggestive of an intestinal parasitic infection but is not specific for *E. histolytica*.

In severe *E. histolytica* infection, the patient may shed pieces of intestinal mucosa. Some patients develop an *ameboma* (amebic granuloma), a tumorlike lesion that forms in the submucosa of the intestine. This represents an area of chronic lysis and infiltration with neutrophils, lymphocytes, and eosinophils. In chronic infections, however, there may be alternating asymptomatic periods and diarrheal episodes.

The characteristic lesion in the intestinal mucosa, a flask-shaped ulcer, is a result of lysis of the intestinal mucosa. The lesion shows a pinpoint ulceration on the mucosal surface and a gradual widening in the submucosal areas and lamina propria as the parasites invade the tissue. The organisms may completely erode the intestinal mucosa and enter the circulation. To survive and colonize the liver, they must resist both antibody and complement activity. Cysteine proteases can inactivate IgG. The trophozoite also uses surface receptor capping—a process of removing surface receptors that have been recognized by antibody. These receptors move to the posterior of the organism and are shed in vesicles. When the trophozoite avoids destruction in the circulation, extraintestinal amebiasis often results. The organ usually colonized is the right lobe of the liver because organisms enter the portal circulation and are then trapped in the venules of the liver. Patients with hepatic abscesses may have symptoms, such as fever, chills, and pain in the upper right quadrant, or they can be asymptomatic. Weight loss, increased WBC counts, or

elevated liver enzyme levels may be present. Jaundice is usually absent. Lung abscesses may be seen as the result of penetration of the diaphragm by amebae from hepatic abscesses or from hematogenous spread. Invasion of the lung can cause the patient to have chest pain, dyspnea, and a productive cough.

Laboratory diagnosis

Patients with diarrhea are most likely to have trophozoites in the stool that may be seen in direct wet mounts or trichrome-stained smears. Sigmoid biopsies may be used to demonstrate the characteristic morphology of the intestinal ulcers or to identify trophozoites in tissue when none can be isolated from the stool specimen. [Table 28.3](#) summarizes the characteristics of *E. histolytica* trophozoites and cysts and compares *E. histolytica* with other amebae. In a direct saline wet mount of a diarrheic stool, the trophozoite of *E. histolytica* may exhibit a progressive, directional motility by extending long, thin pseudopods. The size of the organism ranges from 10 to 50 μm , averaging 15 to 25 μm . The organism is refractile, with the characteristic “bull’s eye” nucleus, consisting of a small central karyosome. Even, fine peripheral chromatin may be only slightly visible.

In a trichrome-stained smear, the cytoplasm of the trophozoite appears clean and free from ingested bacteria and vacuoles. Finely granular nuclear chromatin is evenly distributed on the nuclear membrane, and the small central karyosome stains dark purple-red. Ingested RBCs are diagnostic for *E. histolytica* trophozoites but usually are not seen. If there are no ingested RBCs, the organism must be reported as *E. histolytica*/*E. dispar*. The World Health Organization (WHO) and the Pan American Health Organization recommend that *E. moshkovskii* also be included. Immunoassays are necessary to differentiate these species. [Fig. 28.3](#) shows trichrome-stained trophozoites of *E. histolytica*. The trophozoite in [Fig. 28.3B](#) contains an ingested RBC.

Cysts of *E. histolytica* may have one to four nuclei, each with a small central karyosome and fine, evenly distributed peripheral chromatin. The cytoplasm may occasionally contain chromatoidal bars composed of ribonucleic acid. The average size of the cyst is 10 to 20 μm ([Fig. 28.4](#)). The chromatoidal bars are cigar shaped, with rounded ends. Young cysts often contain multiple bars, and mature cysts may show only one.

Fig. 28.3 A, *Entamoeba histolytica* trophozoite (trichrome stain). B, *E. histolytica* trophozoite. Notice the darkly staining, ingested red blood cell near the nucleus (trichrome stain). (A, $\times 1000$; B, $\times 1000$.)

Table 28.3 Comparisons of amebae

Organism	Trophozoite			Trophozoite and cyst nuclear structure	Cyst			
	Size (μm)	Motility	Cytoplasm		Size (μm) and shape	No. of nuclei in mature cyst	Chromatoidal bars	Glycogen vacuole
<i>Entamoeba histolytica</i> 	15–25	Progressive, directional	Finely granular May contain ingested red blood cells	Small, central karyosome Fine, evenly distributed peripheral chromatin	10–20, round	Four 	Rounded Elongated Usually seen	Not usually seen Diffuse in young cyst
<i>Entamoeba coli</i> 	15–50	Nondirectional	Vacuolated Ingested bacteria	Large, eccentric karyosomes Coarse, uneven peripheral chromatin	15–25, round	Eight 	Elongated Splintered ends Not always seen	Not seen
<i>Entamoeba hartmanni</i> 	4–12	Nondirectional	Finely granular	Small, central karyosomes Fine, evenly distributed peripheral chromatin	5–10, round	Four 	Rounded ends Elongated Not always present	Not seen
<i>Endolimax nana</i> 	5–12	Nondirectional	Vacuolated May contain ingested bacteria	Large, irregularly shaped karyosome No peripheral chromatin	5–12, oval	Four 	Not present	Not seen
<i>Iodamoeba bütschlii</i> 	6–20	Nondirectional	Vacuolated May contain ingested bacteria	Large karyosome surrounded by achromatic granules No peripheral chromatin	6–15, oval or irregular	One 	Not present	Single, defined

In an iodine wet mount, the nuclei appear as yellowish refractile bodies within the cyst; chromatoidal bars do not take up stain and appear as colorless areas. With trichrome stain, the cyst stains light green to gray; nuclear material and chromatoidal bars stain dark purple-red. Young cysts may show discrete glycogen masses that stain light brown in an iodine wet mount, but in the more mature cyst, the glycogen is diffuse. Cysts can persist for 2 to 4 weeks in a moist environment but may be killed by drying, temperatures over 55° C, superchlorination, or addition of iodine to drinking water.

Amebic ulcers of the liver often are detected with ultrasonography or radiography. Subsequent aspiration of the abscess may yield motile trophozoites and necrotic material composed of lysed cells. Serologic methods of detecting antibody to *E. histolytica* are available; the results are positive in more than 90% of patients with extraintestinal disease. The antibody levels increase after tissue invasion but are not protective. Tests for antibodies, however, are not particularly useful in distinguishing between past and current infection because antibodies can persist for years after an infection has resolved. In addition, these tests provide limited information in patients from endemic areas.

Tests that detect *E. histolytica* antigen in stool provide evidence of current infection. Some kits require a large number of organisms to be present for a positive result; however, antigen detection is still considered more sensitive than a microscopic examination of feces. These tests use the EIA method with

monoclonal antibodies to proteins (e.g., serine-rich antigen) or the galactose/*N*-acetylgalactose adhesion lectins. A number of kits detect *E. histolytica* antigens without excluding *E. dispar*; others differentiate *E. histolytica* from *E. dispar*. Point-of-care tests using immunochromatographic techniques assist with the rapid diagnosis of *E. histolytica* infection. Antigen detection assays can be used on other specimens besides feces. For example, testing serum can be effective in diagnosing amebic liver abscess. Multiplex molecular assays for GI syndromic testing are also available, and *E. histolytica* is often included.

Entamoeba hartmanni

E. hartmanni, once known as *small race E. histolytica*, is a nonpathogen. It generally resembles *E. histolytica* in a trichrome-stained smear but is more likely to have an eccentric karyosome or uneven peripheral chromatin resembling that of *Entamoeba coli*. Size is a major determinant in differentiating *E. histolytica* from *E. hartmanni*. The average size of the trophozoites of *E. hartmanni* is 4 to 12 μm ; trophozoites with an average size larger than 12 μm are identified as *E. histolytica* or *E. dispar*. *E. hartmanni* cysts measure 5 to 10 μm ; those of 10 μm or larger are identified as *E. histolytica*, *E. dispar*, or *E. moshkovskii*. Fig. 28.5A shows the trichrome-stained trophozoite, and Fig. 28.5B shows an enlarged view of *E. hartmanni* demonstrating the irregular peripheral chromatin. Fig. 28.6 shows the cyst of *E. hartmanni*, with three nuclei visible and at least one chromatoidal bar.

Fig. 28.4 *Entamoeba histolytica* cyst with round-end chromatoidal bars. Two nuclei are visible (trichrome stain, $\times 1000$).

Fig. 28.6 *Entamoeba hartmanni* cyst (trichrome stain, $\times 1000$).

Fig. 28.5 A, *Entamoeba hartmanni*. Identified by the arrow (trichrome stain). B, Enlarged view of *E. hartmanni* trophozoite. (A, $\times 400$; B, $\times 1000$.)

Entamoeba coli

Entamoeba coli is a commonly found intestinal commensal transmitted by the ingestion of cysts in fecally contaminated food or water. The average size of the trophozoite is 15 to 50 μm , with most measuring 25 μm (Fig. 28.7A). The nuclear structure is characterized by a large eccentric karyosome and coarse, uneven peripheral chromatin on the nuclear membrane. Fig. 28.7B shows an enlargement of the organism demonstrating the characteristic nuclear morphology. The motility of the trophozoite in a wet preparation is sluggish and nondirectional. In a permanently stained preparation, the cytoplasm of the trophozoite may stain a dark purplish gray and contains vacuoles and ingested materials.

The mature cyst has eight nuclei; the immature cyst may have one or two large nuclei, with a large glycogen vacuole. Cysts often stain darkly and unevenly, giving an irregular appearance to the cyst. The large eccentric karyosome is visible, but peripheral chromatin surrounding the entire nucleus may be difficult to see. Chromatoidal bars, when present, have a pointed, splintered appearance. The average size of the cyst is 15 to 25 μm . Fig. 28.8A shows a merthiolate-iodine-formalin wet mount of an *E. coli* cyst, and Fig. 28.8B shows a trichrome-stained cyst.

Endolimax nana

The trophozoite of *E. nana* has a large karyosome, with no peripheral chromatin on the nuclear membrane. The trophozoite ranges in size from 5 to 12 μm , with the average being less

than 10 μm . Fig. 28.9 shows three trophozoites. The cytoplasm is granular and vacuolated. In a wet preparation, the motility is sluggish. In a wet mount, it may be difficult to distinguish the large karyosome of *E. nana* from the karyosome of *E. hartmanni*, and the organisms may be misidentified. The cyst of *E. nana* is oval or spherical, 5 to 12 μm , and has up to four large nuclei (Fig. 28.10). Fig. 28.10B shows an enlargement of the cyst, with three of the characteristic large buttonhole nuclei easily visible. A fourth is partially visible. At least one of the nuclei shows evidence of the thin nuclear membrane.

Iodamoeba bütschlii

Iodamoeba bütschlii is less commonly encountered compared with other nonpathogenic amebae. The nucleus is composed of a single, irregularly shaped karyosome surrounded by achromatic granules and a thin nuclear membrane, with no peripheral chromatin. The trophozoites of *I. bütschlii*, which are 6 to 20 μm in size, show a vacuolated cytoplasm in a permanently stained smear (Fig. 28.11). The oval cyst is 6 to 15 μm (average, 9 to 10 μm) in size and contains a single large karyosome and a large, well-defined glycogen vacuole. The vacuole stains dark brown in an iodine wet mount and appears empty in a permanently stained smear. Fig. 28.12 demonstrates an iron hematoxylin-stained cyst of *I. bütschlii*.

Blastocystis spp.

The taxonomy of *Blastocystis* is unresolved. While originally classified as a yeast, the genus *Blastocystis* has recently

Fig. 28.7 A, *Entamoeba coli* trophozoite. Notice the darkly staining, highly vacuolated cytoplasm (trichrome stain). B, Enlarged view of *Entamoeba coli* trophozoite to demonstrate peripheral chromatin (trichrome stain). (A, $\times 1000$; B, original magnification $\times 1000$.)

Fig. 28.8 A, *Entamoeba coli* cyst (merthiolate-iodine-formalin) wet mount. B, *Entamoeba coli* cyst with five nuclei visible (trichrome stain). (A, $\times 1000$; B, $\times 400$.)

undergone taxonomic reclassification. Genetically, *Blastocystis* spp. closely resemble *Proteromonas lacerate*, a flagellate. However, *Blastocystis* is nonmotile and does not have flagella. Ribosomal ribonucleic acid (rRNA) analysis indicates that it is related to the stramenopiles (brown algae and water molds). Studies indicate that at least 12 different species are found in humans and other animals, and *Blastocystis hominis*

is no longer considered a valid species name. Clinical microbiologists should simply report isolates as *Blastocystis* sp.

Blastocystis is one of the most common intestinal protozoa and has a prevalence rate of greater than 50% in developing countries. Infection occurs in immunocompetent and immunocompromised individuals. *Blastocystis* has come to prominence as a possible cause of diarrhea in humans, although controversy concerning its pathogenicity persists because of conflicting results from numerous studies. Although not considered a common cause of diarrheal disease, this organism,

nevertheless, has been found in patients who have abdominal pain and diarrhea but no other intestinal pathogens. The organism has been associated with chronic infection in some patients. Infected individuals often have a history of travel abroad and, most frequently, of consuming untreated water. Other patients have a history that involves handling of animals. Some studies linked the presence of *B. hominis* to colitis and irritable bowel syndrome (IBS), whereas others have not. Others have suggested that *B. hominis* has no role as a pathogen.

Several subtypes have been identified based on ribosomal DNA (rDNA), which could explain the differences in clinical presentation. The STI-4 strain is seen primarily in humans, whereas other strains are seen in a variety of animals. In addition, the presence of specific cysteine proteases that may function as virulence factors could affect pathogenicity. These proteases are essential for host invasion and trigger proinflammatory cytokines, such as interleukin (IL)-8. Some studies have suggested that certain genotypes may be part of the intestinal microbiota and contribute to intestinal homeostasis. Patients infected with *Blastocystis* may present with diarrhea, abdominal pain, bloating, anorexia, and flatulence. Laboratories often report the presence of the organism quantitatively, with the presence of more than five organisms per high-power field and no other known enteric pathogens in symptomatic patients considered evidence of *Blastocystis* as the cause of GI symptoms.

Blastocystis sp. is a polymorphic organism that exists in four forms: ameboid, granular, central vacuolar (central body form), and cystic. The central body form is the most commonly identified. The life cycle is not completely known, and revisions continue to occur. The cyst is ingested and is infective. The organism excysts in the large intestine, where it transforms into the central vacuolar form. It is not known what triggers the change into other forms. It is known that the organism encysts as stool passes through the large intestine.

The average size for the vacuolar form is 5 to 15 μm , but up to 20% of organisms are smaller than 5 μm , and a few approach 100 μm . The organism is round and has a ring of cytoplasm lining the inside of the plasma membrane, with as many as four nuclei present, which are usually pushed to the side. There is a large central vacuole that occupies up to 90% of the cell volume and may play a role as a storage organelle (Fig. 28.13). The granular form is similar but possesses

granules in the central vacuole and cytoplasm. The ameboid form, which may be seen in diarrheic stools, is 3 to 8 μm and often lacks a vacuole but possesses several pseudopods. In an iodine mount, the cytoplasm and central area of the vacuolar form stain brown. With the trichrome stain, the cytoplasm stains dark green and the central area may stain pale to intensely green, with the nuclei staining dark purple to black. The cyst form can be found in stool and in culture. The cyst stage is small (3 to 5 μm), is oval to round, and possesses one to four nuclei and multiple vacuoles. Because of its small size, it may resemble fecal debris. It is resistant to the usual chlorine levels in drinking water, and water has been implicated in transmission of the organism.

Tissue amebae

Free-living, thermotolerant amebae can tolerate a wide range of temperatures, pH, and salinity. They are found in soil and water (e.g., freshwater sources, domestic water supplies, sewage, swimming pools), usually feeding on bacteria in the environment, but are known to cause human disease. They can gain access to the CNS by inhalation into the upper respiratory tract followed by penetration of the nasal mucosa, which allows them to travel along the olfactory nerve to the brain, or by hematogenous spread from the lungs or skin lesions. Although the number of infections caused by these organisms is low compared with those caused by intestinal protozoans, they are very difficult to diagnose and treat and are associated with a high mortality rate. *Naegleria fowleri* and *Acanthamoeba* spp. have been recognized for many years as the amebae most commonly associated with CNS invasion in humans. The media sometimes refer to *N. fowleri* as the "brain-eating ameba."

The ameboflagellate *N. fowleri* is the only one of about 30 species of *Naegleria* that has been identified as a human pathogen. It is the causative agent of primary amebic meningoencephalitis (PAM), a rapidly fatal condition involving the CNS. *Acanthamoeba* spp. have been associated with a more chronic condition, granulomatous amebic encephalitis (GAE), especially in individuals with impaired cell-mediated immunity. In addition, *Acanthamoeba* spp. have been linked with amebic keratitis in soft contact lens wearers and with

Table 28.4 Comparison of central nervous system infections caused by amebae

Parameter	Primary amebic meningoencephalitis	Granulomatous amebic encephalitis
Causative agent	<i>Naegleria fowleri</i>	<i>Acanthamoeba</i> spp. and <i>Balamuthia mandrillaris</i> ^a
Stages in:		
Cerebrospinal fluid	Trophozoite	Trophozoite
Brain biopsy	Trophozoite	Trophozoite and cyst
Characteristics	Trophozoite, 10–35 μ m Large karyosome Broad pseudopods	Trophozoite, 15–45 μ m Spinelike pseudopod Cyst, 15–20 μ m Wrinkled double wall
Entry	Nasal passage—olfactory nerve to CNS	Lungs and skin with hematogenous spread to CNS
Clinical course	Fulminant (death within 1 week of onset)	Slow and chronic
Population at risk	Children to young adults, healthy (history of water activities in stagnant, warm water)	Immunocompromised
CNS, Central nervous system.		
^a The pathogenesis and morphology of <i>Acanthamoeba</i> spp. and <i>Balamuthia mandrillaris</i> are similar. In some cases, <i>Balamuthia</i> appears to have more than one nucleolus in tissue sections compared to one found in <i>Acanthamoeba</i> .		

cutaneous infections in patients with acquired immunodeficiency syndrome (AIDS). A comparison of the CNS infections caused by *N. fowleri* and *Acanthamoeba* spp. is provided in Table 28.4. *Balamuthia mandrillaris*, another free-living ameba, is primarily associated with GAE and cutaneous lesions in humans. In addition, *Sappinia* spp. and *Paravahlkampfia francinae*, also free-living amebae, have been identified in rare cases of encephalitis and meningitis.

Naegleria fowleri

Although PAM has been reported from many countries worldwide, it is a relatively rare infection. However, many studies have shown the presence of antibodies directed against *N. fowleri* in healthy individuals. In the United States, between 1962 and 2021, there were 154 reported cases, with only four survivors. PAM is most frequently reported in Texas (40 cases), Florida (36 cases), and California (10 cases) but has been reported as far north as Minnesota. It occurs in healthy, immunocompetent children and young adults with no predisposing condition. A common factor in infection is the report of recent swimming or other water-related activities in warm, artificial lakes or brackish or muddy water or exposure to bottom sediment. Waterskiing, wakeboarding, or other activities that increase the chances of forceful entry of water into the nose may facilitate infection. It is not known why only a few individuals are infected in spite of such

common exposure. In recent years, there have been several cases related to sinus irrigation using tap water.

The life cycle of *N. fowleri* is relatively simple, consisting of three stages: (1) free-living amebic trophozoite, (2) transient flagellate form that appears when there is a scarcity of nutrients, and (3) environmentally resistant cyst. The trophozoite enters the nasal cavity through inhalation of contaminated water or soil. The amebic form colonizes the nasal cavity, invades the nasal mucosa, attaches to olfactory nerves, penetrates the cribriform plate, moves along the olfactory nerve to the olfactory bulb, and moves into the arachnoid space. From there, it is free to spread throughout the CNS. Infections are thought to be related to inhalation of a large number of organisms or forceful entry of water into the nose (microtrauma) and to the virulence of the strain.

Clinical infection

Clinically, the disease cannot be distinguished from bacterial meningitis. The incubation period is usually 2 to 3 days but may range up to 2 weeks. Initial symptoms include severe bifrontal headache, fever (38° to 41° C), stiff neck, and nausea and vomiting. CSF will show evidence of increased intracranial pressure, increased levels of neutrophils and protein, and decreased glucose levels. In the late stages, there may be increased numbers of RBCs in the CSF. The organism multiplies in brain tissue, and within 2 to 4 days, the patient can experience drowsiness, confusion, and seizures that can progress to coma. The disease is usually fatal within 1 week of the appearance of clinical symptoms. At autopsy, there will be evidence of trophozoites along with a purulent exudate, edema, and hemorrhagic and necrotic areas of infection in the brain.

N. fowleri is capable of direct cell-to-cell damage resulting in destruction of erythrocytes and other cells, including nerve cells. The invasive properties of the organism are related to its ability to secrete cytotoxic enzymes (e.g., phospholipase, sphingomyelinase) and induce generation of proinflammatory cytokines that facilitate tissue destruction. Macrophages and neutrophils are the primary host defense against the organism because the trophozoites are relatively resistant to the actions of host cytokines. Infection with *N. fowleri* has greater than 95% mortality. Because the symptoms resemble those of bacterial meningitis, specific treatment may be delayed, yet the possibility of cure depends on early diagnosis. Aggressive therapy with intravenous and intrathecal administration of amphotericin B has been used. Rifampin, miconazole, or fluconazole and azithromycin have been used in addition to amphotericin B. Survival in several cases has been linked to additional procedures, including use of medically induced hypothermia and the experimental drug miltefosine.

Laboratory diagnosis

Diagnosis can be made by finding motile amebic trophozoites in CSF. The trophozoite ranges in size from 10 to 35 μ m and moves by explosively extending large, broad pseudopods (lobopodia). The nucleus contains a large central karyosome that is surrounded by a halo. Fig. 28.14 shows a trophozoite of *N. fowleri* as it appears in a CSF specimen stained with iron hematoxylin. In PAM, CSF contains many segmented neutrophils and RBCs and demonstrates elevated protein levels and normal to decreased glucose levels, which are characteristic of bacterial meningitis.

Fig. 28.14 *Naegleria fowleri* trophozoite. Note the prominent karyosome (iron hematoxylin stain, magnification $\times 1000$).

N. fowleri does not stain well with Gram stain, but motile trophozoites can be seen in a wet mount of CSF. They must be carefully distinguished from leukocytes. The trophozoite may also be seen in cytocentrifuged CSF specimens stained with Wright stain. The ameba can be converted to the flagellate stage by adding one drop of CSF sediment to 1 mL of distilled water and incubating it at 37° C. Conversion to the flagellate form occurs in 2 to 20 hours. The organisms can be cultured by overlaying nonnutrient agar with *Escherichia coli* and inoculating the agar with a drop of the CSF sediment and incubating it at 37° C. Clearing of the agar in thin tracks is evidence of the organism feeding on the bacteria. Trophozoites may be observed microscopically. Cysts, which are approximately 10 μm in diameter and have a round, smooth double wall and a single pore, are not seen in clinical specimens. Immunofluorescent staining of CSF with monoclonal antibody can be done in some reference laboratories for detection of the trophozoite. Molecular methods are used to identify strains.

Acanthamoeba

Acanthamoeba spp. have been linked to several clinical conditions, including GAE, cutaneous infections, and amebic keratitis. They have also been identified as the host for several pathogenic bacteria, such as *Legionella* spp., *Vibrio cholerae*, and *Escherichia coli* O157, but the role these may play—if any—in pathogenicity is unknown. Cutaneous acanthamebiasis has been associated primarily with patients with AIDS whose CD4 count is less than 250/ μL . The condition is characterized by chronic nonhealing lesions that may present as nodules, papules, or ulcerations, especially on the extremities and the face. Lesions may develop at the site of inoculation or may occur as a result of hematogenous dissemination from the lungs. Trophozoites and cysts can be seen in biopsy preparations of the lesion. Although it is possible for *Acanthamoeba* spp. to enter the CNS through the nasal passage, the organisms are characterized by hematogenous spread to the CNS from a primary inoculation site in the lungs or skin. The organism penetrates the blood-brain barrier because of changes in the endothelial cell barrier caused by the interaction of the parasitic enzymes and host cytokines.

GAE is subacute; the incubation time is unknown but may range from months to years. Symptoms may include drowsiness, seizures, loss of reflex activity, hemiparesis, headache,

Fig. 28.15 Cornea, scraping, calcofluor white stain, fluorescence microscopy. Polyhedral parasitic cyst (13 μm). Morphology consistent with *Acanthamoeba* cyst.

stiff neck, and personality disorders. The trophozoite is uncommonly seen in CSF, and diagnosis is typically made by brain biopsy demonstrating cysts, trophozoites, or both. Histologic preparations of the brain at autopsy show inflammatory lesions containing many segmented neutrophils, eosinophils, and trophozoites. A specific therapeutic regimen has not been established because most infections have been diagnosed at autopsy. However, disseminated *Acanthamoeba* infections have been treated with amphotericin B, pentamidine isethionate, fluconazole, ketoconazole, and co-trimoxazole (trimethoprim-sulfamethoxazole).

Amebic keratitis, associated with *Acanthamoeba* spp., has been identified in immunocompetent individuals since the 1980s. Individuals who wear contact lenses, especially the soft and extended-wear types, are the primary at-risk group, with greater than 80% of the cases identified. Factors in these infections include improper storage and disinfection procedures, a history of corneal trauma, or wearing contact lenses during swimming, all of which may cause corneal trauma and subsequent colonization by the organism. The organism binds directly to corneal epithelium via acanthopodia and produces proteases and other enzymes that cause cell lysis. Patients experience photophobia, blurred vision, inflammation, ring infiltrates, and pain. Because of the similarity in tissue damage, the infection may initially be confused with bacterial or herpes simplex virus infection, delaying treatment. Phase-contrast microscopy of direct wet mount preparations of corneal scrapings can reveal the trophozoite or cyst. The use of calcofluor white increases detection of the organisms (Fig. 28.15). Permanent stains, such as trichrome and Wright-Giemsa stains, may also demonstrate the trophozoite in clinical specimens (Fig. 28.16).

Isolation of *Acanthamoeba* may be performed in a manner similar to that for *N. fowleri*. *Acanthamoeba* spp. have only two stages: the resistant cyst and the motile trophozoite. The trophozoite ranges from 15 to 45 μm in diameter and has a single nucleus, with a central prominent endosome. Blunt pseudopods and characteristic spinelike projections of the cytoplasm (acanthopodia) may also be seen on a wet mount. The cyst is approximately 15 to 20 μm , spherical, and double walled, with the walls having a wrinkled appearance. Topical applications of chlorhexidine gluconate and ketoconazole have been used to treat cutaneous infections. Corticosteroids are used to reduce inflammation. Despite treatment, patients

with systemic infections have a poor prognosis, and many patients with keratitis lose their sight in the affected eye.

Balamuthia mandrillaris

B. mandrillaris is an emerging opportunistic pathogen that has been identified as a cause of skin lesions and GAE. Unlike *Acanthamoeba*, which has a wide distribution, this organism is found primarily in soil. From 1990 (when it was first linked to human illness) to 2019, this free-living amoeba has caused more than 200 cases worldwide and about 100 cases in the United States. The mortality rate is greater than 95%. In the United States, more than 50% of cases reported occurred in individuals of Hispanic origin. It is unknown if there is a genetic predisposition or if the type of work in which the individuals engage increases exposure risk. Unlike infections with *Acanthamoeba* spp., which occur primarily in immunocompromised hosts, infection with *B. mandrillaris* can occur in immunocompetent and immunocompromised individuals. Humans become infected by inhaling airborne cysts of the organism or by direct inoculation through skin lesions. There have been several reported cases of transmission via organ transplants. No person-to-person spread has been documented.

Skin infections present as a relatively painless nodule. Once the encephalotropic organism has entered the body through the lungs or skin, it spreads hematogenously. Only rarely will it invade the body nasally and spread along nerve fibers to

the olfactory bulb. Once the organism reaches the blood-brain barrier, it is able to bind to microvascular endothelial cells through receptor molecules. The organism produces proteolytic enzymes such as collagenases and metalloproteases that facilitate tissue damage, and the host's inflammatory response helps increase the permeability of the barrier. In the CNS, the organism multiplies by binary fission and causes a necrotizing hemorrhagic infection similar to that caused by *Acanthamoeba* spp. The onset is insidious, with fever, headache, stiff neck, vomiting, and photophobia, and progresses to personality changes and seizures. Onset of symptoms can occur weeks to months after infection, but when the brain is affected, the time to death is short. Treatment involves a multiple antimicrobial regimen, including fluconazole, clarithromycin, and sulfadiazine.

In most cases, infection is identified at autopsy by finding trophozoites and cysts in the tissue. The trophozoite is 30 to 60 μm in diameter, with broad pseudopods and a large single nucleus, with multiple nucleoli. The cyst is round, 10 to 30 μm in diameter, and it has a single nucleus and is multiwalled. The CSF will usually exhibit increased protein levels, normal or decreased glucose levels, and increased levels of lymphocytes. The culture methods using nonnutritive agar seeded with *Escherichia coli* are nonproductive because this organism will not feed on gram-negative bacteria. Immunohistochemical or nucleic acid assays are often needed to identify *B. mandrillaris*.

Fig. 28.16 Cornea, scraping, Wright-Giemsa stain, light microscopy Parasitic precyst (13 μm) (arrow). Morphology consistent with *Acanthamoeba* spp.

Ciliates

Only one ciliate, *Neobalantidium coli* (formerly *Balantidium coli*), is considered pathogenic for humans. Pigs are the natural host for this organism, and humans serve as accidental hosts. The organism lives in the large intestine, where it may cause mucosal lesions but not extraintestinal infections. Most people with this infection are asymptomatic, but the organism can cause a self-limiting diarrhea with nausea, vomiting, and abdominal tenderness.

The life cycle is similar to that of the amoebae, with the cyst being the infective stage. This is the largest of the protozoa, and the trophozoite is covered with short cilia. The oval trophozoite (Fig. 28.17A) demonstrates two size ranges: (1) 45 to 60 μm $\times$ 30 to 40 μm and (2) 90 to 120 μm $\times$ 60 to 80 μm .

Fig. 28.17 A, *Balantidium coli* trophozoite. The arrow denotes the cytostome (trichrome stain). B, *B. coli* cyst (trichrome stain). (A, $\times 200$; B, $\times 200$.)

The cilia-lined **cytostome** is located at the slightly pointed anterior end. The cytoplasm contains food vacuoles. A small opening at the posterior, the *cytopyge*, is used to expel the contents of food vacuoles. In a wet mount, the cilia are seen propelling the organism with a rotary motion. The rounded, thick-walled cyst (see Fig. 28.17B) averages 45 to 75 μm . Cilia may be seen retracted within the cyst wall. Both stages are characterized by the presence of two nuclei, a kidney bean-shaped macronucleus, and a small, round micronucleus that is usually situated in the small curvature of the macronucleus. The micronucleus is rarely visible in routinely stained smears. Although this is the largest of protozoa, it can be missed during microscopic examination because laboratory scientists are trained to search for protozoan shapes that are typically much smaller.

Pathogenic intestinal and urogenital flagellates

The flagellates constitute another major group of parasites that can inhabit the intestinal tract. The life cycle is relatively simple, resembling that of the amebae (Fig. 28.18). Most flagellates have both cyst and trophozoite stages. *Dientamoeba fragilis*, *T. vaginalis*, and *Trichomonas hominis* lack a cyst stage, however, and the trophozoite of these organisms serves as the infective stage.

Giardia duodenalis, also known as *Giardia intestinalis* or *Giardia lamblia*, originally was considered the only pathogenic intestinal flagellate. However, *D. fragilis* is now recognized as a pathogen. *T. vaginalis* is a pathogen of the genitourinary

tract in men and women. Table 28.5 shows the characteristics of the trophozoite and cyst stages of the intestinal and genitourinary flagellates.

Giardia duodenalis

G. duodenalis has a worldwide distribution and has frequently been identified as the causative agent of outbreaks of gastroenteritis and traveler's diarrhea. It is the most commonly reported intestinal protozoan in the United States. The prevalence rate in underdeveloped countries ranges from 20% to 30%, and the organism is now included in the WHO Neglected Disease Initiative. The main groups at risk for infection are travelers returning from endemic areas, hikers who drink untreated water from streams, and children in daycare centers. Travelers in areas with poor sanitation are often exposed to conditions in which waterborne or foodborne (rare) cysts are ingested. Outbreaks have been reported from swimming pools contaminated with feces. Cysts may remain viable for several months in cold water. They are somewhat resistant to chlorine and iodine, but they are susceptible to desiccation and heating to 50° C.

Some animals, such as beavers, may serve as reservoirs and can be a source of infection for backpackers who drink from streams or rivers. The terms *beaver fever* and *backpacker's diarrhea* have been used to describe the condition in this group of people. Children younger than 5 years of age are at risk for infection, and *G. duodenalis* has caused outbreaks of diarrhea in nurseries and daycare centers as a result of person-to-person contact. Along with *E. histolytica*, *G. duodenalis* has been identified as a sexually transmitted pathogen among those who practice oral-anal sex.

Clinical infection

A low number of cysts, as few as 10, can initiate infection with *G. duodenalis*. Once the cysts are ingested, the gastric acid in the stomach triggers the beginning of excystation. The organism then responds to the slightly alkaline pH in the small intestine and completes the excystation process in the duodenal area, in which the presence of carbohydrates and bile stimulates growth of the trophozoite. Although it does not invade the mucosal surface, it does attach to the surface of columnar epithelial cells. Adherence to the intestinal mucosa is achieved by the ventral sucking disk. Pathologic mechanisms associated with *G. duodenalis* include a mix of human and organism factors. These result in irritation and damage to the mucosa, as well as interference with absorption of nutrients, fats, and fat-soluble vitamins. No toxins or virulence factors have been identified but, there is evidence of inflammatory cell infiltration.

There are eight genetic assemblages—A to H—identified, with subtypes A1 and A2, and B affecting humans. Strain A has a large number of variant surface proteins (VSPs) that can be altered and thus involved in parasite evasion of the host immune response. The intestinal mucous layer; host proteases and lipases; peptides such as defensin and lactoferrin; the presence of secretory IgA; and the influx of mast cells that produce ILs, such as IL-6, help prevent colonization by the organism. The organism increases apoptosis of intestinal cells via caspases, leading to shortening of the intestinal brush border. Damage to the mucosal surface results in atrophy of the microvilli. Bacterial overgrowth may contribute to symptoms.

Fig. 28.18 Generalized life cycle for intestinal flagellates.

Table 28.5 Comparison of intestinal and urogenital flagellates

Organism	Trophozoite				Cyst		
	Size (μm)	Motility	No. of nuclei	Other features	Size (μm) and shape	No. of nuclei	Other features
<i>Giardia duodenalis</i> 	9–21 × 5–15	Falling leaf	Two	Sucking disk, ventral surface Parabasal bodies and axonemes	8–12, oval	Four	Cytoplasm retracted from cyst wall Fibrils and flagella inside cyst
<i>Chilomastix mesnili</i> 	10–20 × 3–10	Rotary	One	Spiral groove Cytostome	6–10, lemon-shaped	One	Anterior of cyst has nipple-like protrusion
<i>Trichomonas hominis</i> 	6–14	Jerky	One	Undulating membrane the entire length of the organism Axostyle through body			No cyst stage
<i>Dientamoeba fragilis</i> 	5–12	Nondirectional	Two (20% have one)	Nucleus made of four to eight clustered granules Resembles amoeba			No cyst stage
<i>Trichomonas vaginalis</i> 	7–23 × 5–12; average, 15–18	Jerky, nondirectional	One	Undulating membrane half the length of the body Found in urine			No cyst stage

Clinical presentation ranges from asymptomatic infection to acute infection or chronic infection. In most patients, the acute infection manifests as self-limiting diarrhea, with malaise, cramps, nausea, and abdominal tenderness after an incubation period of 12 to 14 days. Explosive, foul-smelling, nonbloody diarrhea is present, while fever and evidence of inflammation are absent. Symptoms last 1 to 4 weeks, and the patient may lose a significant amount of weight. Patients with secretory IgA deficiency or achlorhydria seem not only to be more apt to acquire the infection but also to develop chronic disease. In chronic giardiasis, there may be a malabsorption-like syndrome, with up to 20% weight loss, fatigue, anorexia, and steatorrhea with large amounts of gas. Fats and vitamin B₁₂ are two of the substances that may be incompletely absorbed in chronic infection, but macrocytic anemia is not common. Children 6 months to 5 years of age are most susceptible to metabolic problems, including iron deficiency, protein malnutrition, and micronutrient deficiency. They may also demonstrate growth and cognitive delay or general failure to thrive. Children with preexisting malnutrition are more likely to develop long-term complications. There have been suggestions that there may also be postinfection complications, such as IBS or reactive arthritis in some individuals. Metronidazole (Flagyl), which has been the drug of choice for treating giardiasis, may be prescribed. Albendazole is another drug that may be used.

Laboratory diagnosis

Feces serve as the usual diagnostic specimen, but shedding of the cysts is irregular, and multiple stool specimens are often required for diagnosis. The trophozoites of *G. duodenalis* are pear shaped or teardrop shaped, have bilateral symmetry, and measure approximately 9 to 21 μm $\times$ 5 to 15 μm . They show a characteristic “falling leaf” motility in a wet mount. In a permanently stained smear, the binucleate organism has been described as having an “old man appearance” (Fig. 28.19A). Two oval nuclei, each with a large central karyosome, are on each side of the midline. Four pairs of flagella, midline axonemes, and two median bodies posterior to the nuclei are also present. A large ventral sucking disk composed of microtubules is used by the organism to attach itself to the intestinal wall. The organism often stains faintly with trichrome stain. Fig. 28.19B shows an enlargement of the trophozoite that reveals several morphologic features. Table 28.5 summarizes the characteristics of *G. duodenalis* and compares them with those of other flagellates. Cysts of *G. duodenalis* are oval and measure approximately 8 to 12 μm $\times$ 7 to 10 μm . There are up to four nuclei, and the cytoplasm is often pulled away from the cyst wall. On a permanently stained smear, the retracted flagella and other internal structures give the cyst a cluttered appearance. Fig. 28.20 show the presence of several cysts of *G. duodenalis*.

EIAs using monoclonal antibodies to detect soluble antigens of *G. duodenalis* in stool are available. Newer lateral flow

Fig. 28.19 A, *Giardia duodenalis* trophozoite, identified by the arrow (trichrome stain). B, Enlarged view of *G. duodenalis* trophozoite (trichrome stain). (A, $\times 1000$; B, original magnification, $\times 1000$.)

Fig. 28.20 A, *Giardia duodenalis* cysts (arrow). B, *Giardia duodenalis* cysts (arrows). (A, Trichrome stain, $\times 1000$; B, trichrome stain, $\times 1000$.)

immunochromatographic tests that may detect *E. histolytica* and/or *Cryptosporidium* spp. provide results in 15 minutes. DFA tests can be used to identify the cyst of *Giardia* in a stool specimen. Several of these DFA tests also contain a monoclonal antibody that identifies *Cryptosporidium*. The antigen detection assays have a sensitivity of 63% to 100% and a specificity from 90% to 100%. When clinical symptoms persist and the organism cannot be demonstrated in feces or when the patient does not respond to treatment, duodenal aspiration or the Entero-Test has been used to detect the organism.

Dientamoeba fragilis

D. fragilis has a worldwide distribution, with prevalence ranging from less than 1% to greater than 40%. For many years, there were questions about the pathogenicity of *D. fragilis*. The organism was isolated from the stools of patients who were asymptomatic and from those who had GI symptoms, such as abdominal pain or tenderness and diarrhea. Evidence now suggests that the organism has a role as a pathogen in either acute or chronic infections. As with *Blastocystis* infections, links to IBS or irritable bowel disease have been suggested. Case reports show that treatment with metronidazole results in the clearance of the organism and alleviation of symptoms.

Molecular methods show that there are at least two genotypes. While their significance is unknown, genotype 1 is more common. The organism was historically described as lacking a cyst stage, but recent animal studies have identified a cystlike structure in feces. The life span of the trophozoite outside the body is very short, so direct transmission is unlikely. Foodborne or waterborne outbreaks are not common, but some infections have been seen in family groups. Controversy about transmission exists in research studies. Some studies suggest that the trophozoite may be transmitted to humans through ingestion of helminth eggs, especially those of *Enterobius vermicularis*, because co-infection of *D. fragilis* and *E. vermicularis* is more common than co-infection of *D. fragilis* and other organisms. Some, but not all, molecular studies have shown evidence of *D. fragilis* DNA within the pinworm egg. Whether the cystlike structure can be confirmed as the transmission stage remains to be determined.

The morphology of *D. fragilis* closely resembles that of the amebae, hence the name, but electron microscopy studies of ultrastructure, small-subunit rRNA gene analysis, and the lack of a cyst stage all indicate that it is closely related to the trichomonads. *D. fragilis* has apparently permanently lost its flagella. The organism is characteristically binucleate, with 50% to 80% of organisms demonstrating this characteristic. The delicate nuclear membrane has no peripheral chromatin, and the karyosome consists of four to eight discrete granules, one of which is often larger than the others. The size of the trophozoite ranges from 5 to 12 μm , and the cytoplasm contains many food vacuoles and bacteria (Fig. 28.21). This organism degenerates within hours after excretion, and rapid preservation of the stool is important. Since trophozoites do not usually survive the concentration technique, they will only be detected on a permanent stained smear. *D. fragilis* can be difficult to see on a trichrome-stained smear because its outline is often indistinct and blends into the background. No commercial tests are available for *D. fragilis* antigen in stool, so microscopy remains the method of choice.

Fig. 28.21 *Dientamoeba fragilis* binucleate trophozoite, identified by the arrow (trichrome stain, $\times 1000$).

Trichomonas vaginalis

T. vaginalis, a pathogen of the urogenital tract in men and women, causes trichomoniasis, one of the most common, nonviral, sexually transmitted diseases (STDs), with an estimate of 180 million cases worldwide. Approximately 3 million to 5 million new cases are reported in the United States each year, with up to two thirds of these occurring in women 15 to 24 years of age. Humans are the only host, and the presence of infection with the organism is associated with other STDs, especially gonorrhea. Trichomoniasis has been increasingly associated with adverse pregnancy outcomes, including transmission of the organism to the newborn, in addition to cervical neoplasia and pelvic inflammatory disease. The most significant complication is increased risk of HIV transmission primarily because of the inflammatory response that compromises the mucosal barriers to HIV. *T. vaginalis* lacks a cyst stage, and the trophozoite stage is infective through sexual contact. The pear-shaped trophozoite assumes an ameboid form on contact with epithelial cells of the genital tract. Adhesion molecules, known as *lipoglycans*, mediate this binding. The organism is susceptible to rapid drying in the environment, but a few cases of nonsexual transmission have been reported.

In women, the infection is primarily localized to the vagina, resulting in itching and the production of a frothy, creamy, mucopurulent vaginal discharge as well as dysuria. About one third of infected women, however, are asymptomatic. A chronic state can develop, with mild symptoms of pruritus and scanty discharge. Women with chronic infection are often a major source of transmission to sexual partners. Men infected with *T. vaginalis* are usually asymptomatic and serve as carriers, although they can develop nonspecific urethritis with a milky discharge that lasts up to 4 weeks. *T. vaginalis* is now considered an important cause of nongonococcal urethritis. Long-term immunity is not developed after an acute infection, and reinfection can occur.

The diagnosis in women is typically made by finding the trophozoite in vaginal discharge or occasionally in urine; in men, the trophozoite is seen in urine or prostatic secretions. The organism is 5 to 18 μm in diameter and has four anterior flagella and an **undulating membrane** that extends one half the length of the body. In a wet mount, the trophozoite has a characteristic jerky motility, and the motion of the flagella and undulating membrane may be seen. The preparation should be examined

immediately because the organism loses viability quickly. In a Giemsa-stained preparation, the pear-shaped organism shows the presence of an axostyle extending the length of the organism, a single nucleus near the anterior end, and chromatic granules extending the length of the axostyle. Fluorescent staining of exudates using acridine orange will demonstrate a typical fluorescent morphology with a yellow to green nucleus. Although most clinicians rely on wet mount preparations, the method has relatively low sensitivity (30% to 70%).

Until the advent of molecular methods, culture of the organism from exudate was considered the most sensitive and specific method of detection, although an inoculum of 300 to 500 organisms is necessary. Commercial systems using a plastic pouch containing culture medium are available for detection of the organisms. The specimen should be inoculated into the pouch within 30 minutes of collection to ensure optimal viability of the organism. Culture specimens should be held for up to 5 days and then examined microscopically through the pouch. PCR methods and antigen detection assays are also commercially available. Rapid antigen detection tests are based on immunochromatographic EIA procedures using monoclonal antibodies. These tests have relatively high sensitivity compared with examination of a wet preparation and often test for more than one agent of vaginal infection. PCR tests are especially useful in detecting infection in asymptomatic men. Infections are usually treated with metronidazole. Treatment of sexual partners is suggested to obtain optimal cure and prevent reinfection.

Nonpathogenic intestinal flagellates

Chilomastix mesnili and *Pentatrichomonas* (*Trichomonas*) *hominis* are intestinal nonpathogens that must be differentiated from pathogenic flagellates. *C. mesnili* trophozoites are pear shaped and approximately 10 to 20 μm long $\times$ 3 to 10 μm wide. The cytostome and nucleus are prominent in the anterior of the organism, and a spiral groove encircles the body of the organism. The nucleus has a small central karyosome and is surrounded by fibrils that curl around the cytostome to give a so-called “shepherd’s crook” appearance. The cytostome is elongated and rounded at the anterior and posterior. The cyst of *C. mesnili*, which measures 6 to 10 μm , is lemon shaped and has an anterior nipple. The nucleus, cytostome, and curved fibrils are visible in a stained smear (Fig. 28.22).

Fig. 28.22 *Chilomastix mesnili* cyst, identified by the arrow (trichrome stain, $\times 1000$).

The *P. hominis* trophozoite is 6 to 14 μm long, with a prominent axostyle extending through the posterior of the organism, four anterior flagella, and an oval nucleus with a small karyosome. The undulating membrane extends the length of the organism and is joined to the body along the costa. Trophozoites stain weakly, making them difficult to detect on stained smears. *Enteromonas hominis* and *Retortamonas intestinalis* are two additional nonpathogenic flagellates occasionally found in clinical specimens.

Case check 28.1

The intermittent bouts of diarrhea in the young patient in the Case in Point could be caused by any organism—viral, bacterial, or parasitic. The culture results were negative, so that would seemingly rule out a bacterial cause. Viral agents are not routinely cultured, nor would we expect viral causes to extend for such a long period. Stools from patients with parasitic infections caused by *G. duodenalis* are usually characterized as having a pale, frothy, gassy, and greasy appearance. Stools from patients with symptomatic amebiasis caused by *E. histolytica* often demonstrate blood. Neither organism is associated with *pica* (eating dirt or other nonfood material). In general, infections with protozoa do not cause eosinophilia.

Blood and tissue flagellates

The hemoflagellates in the genera *Leishmania* and *Trypanosoma* differ in several ways from the intestinal flagellates. First, they are transmitted by insect **vectors**, organisms that can transmit disease-causing agents. These vectors are necessary for completion of the life cycle. Second, these organisms have different life cycle stages for diagnosis. Fig. 28.23 shows the four life cycle stages of the hemoflagellates. The trypomastigote and amastigote are the diagnostic stages found in humans. The amastigote is an obligate intracellular organism, 2 to 5 μm in diameter, found within macrophages and liver, spleen, or bone marrow cells in diseases caused by *Leishmania* spp. In addition, the amastigote stage may be seen in cardiac or GI cells of patients infected with *Trypanosoma cruzi*. The trypomastigote, a flagellated form measuring 15 to 20 μm in size, is found in the blood, lymphatic fluid, and CSF of patients infected by *Trypanosoma* spp. The epimastigote and promastigote stages are seen in the insect vectors.

Leishmania

The genus *Leishmania* contains several complexes of at least 20 species that cause disease in humans: *Leishmania tropica*, *Leishmania mexicana*, *Leishmania braziliensis*, and *Leishmania donovani* complexes. Leishmaniasis is a zoonotic infection in which dogs and rodents serve as the primary reservoir hosts for all species, and humans serve as an accidental host. The insect vectors are sand flies of the genera *Phlebotomus* and *Lutzomyia*.

Clinical infections

Clinical infections range from single, self-healing skin ulcers to visceral disease affecting multiple organs. *L. tropica* complex, the cause of cutaneous leishmaniasis, or Oriental sore, is found primarily in the Far East and North and Central Africa. The condition is characterized by the presence of a crusted

Fig. 28.23 Life cycle stages of the blood and tissue flagellates.

circular lesion on any exposed body surface, especially the face and extremities. The lesion begins as a small, red papule at the site of the insect bite and progresses to a lesion with an elevated indurated margin that may reach 8 cm. The lesion resolves in several months and provides incomplete immunity against future infection. *L. mexicana* complex, the cause of New World cutaneous leishmaniasis, is found in South and Central America. Another form of the disease, chiclero ulcer—often associated with *L. mexicana* complex—is characterized by lesions on the ear. The infection is self-limiting and does not invade mucosal surfaces, but secondary bacterial infection can occur.

L. braziliensis complex is the causative agent of mucocutaneous leishmaniasis, or espundia. This infection manifests itself as an initial lesion that may increase in size, invading and destroying the mucosal surfaces of the nose and mouth. It may also destroy cartilage, leaving the patient with significant disfigurement. *L. braziliensis* complex is found primarily in Mexico and Central and South America.

The most severe infection, visceral leishmaniasis, or kala-azar, is endemic in parts of South America, Africa, southern Europe, and Asia, and it commonly affects children. The causative agents are organisms of the *L. donovani* complex. In this disease, organisms spread through the lymphatics and invade organs of the reticuloendothelial system, including the liver, spleen, lymph nodes, and bone marrow. Patients with kala-azar exhibit malaise, anorexia, weight loss, headache, and fever. In addition, they may show splenomegaly and hepatomegaly with elevated liver enzyme levels, hypogammaglobulinemia, and hypoproteinemia. *Leishmania*-containing macrophages invade the bone marrow. The kidneys and heart may also be affected.

A few patients experience a nodular or macular rash, known as *post-kala-azar dermal leishmaniasis*, on the face, trunk, and limbs months to years after treatment. If untreated, visceral leishmaniasis is often fatal within 2 years. Cases of cutaneous leishmaniasis and visceral leishmaniasis have been

seen in several military personnel serving in Middle Eastern countries, such as Iraq and Afghanistan. Visceral leishmaniasis has also been reported to be transmitted through solid organ transplants. Previously, standard therapy for all leishmanial infections was pentavalent antimony compounds. However, liposomal amphotericin B and paromomycin were used in the past few years. A new drug, miltefosine, has been successful in treating infections.

Life cycle

Fig. 28.24 shows the generalized life cycle for *Leishmania* spp. When the female insect takes a blood meal, she ingests the amastigote stage. The parasite develops as a promastigote in the gut of the insect and migrates to the salivary glands when mature. The promastigote is transmitted to humans through the salivary glands of the insect when it takes a blood meal. The promastigote is inoculated into the dermal-epidermal junction and taken up via receptor-mediated phagocytosis by a macrophage. Within the macrophage, it converts to the amastigote stage and multiplies within the cell. When the cell ruptures, amastigotes are released and invade other macrophages. Parasite and immune cell interactions may lead to an inflammatory response that controls the parasite but also causes tissue damage.

Laboratory diagnosis

The amastigote is the diagnostic stage in humans. It is a small intracellular stage found in macrophages or histiocytes around the periphery of the skin lesions (*L. tropica* or *L. braziliensis*) or within cells of a bone marrow aspirate or liver or spleen biopsy specimen (*L. donovani*). Wright staining of bone marrow aspirate reveals an oval organism 2 to 5 μm in diameter, with pale blue cytoplasm, a large red nucleus, and a rodlike **kinetoplast** (a structure rich in DNA associated with the basal body near the base of the flagellum) within the cytoplasm (Fig. 28.25). The amastigote has also been reported extracellularly in cases of cutaneous leishmaniasis.

Fig. 28.24 Life cycle of *Leishmania* spp.

Fig. 28.25 Amastigotes of *Leishmania* spp., identified by arrows (Giemsa stain, $\times 1000$).

Promastigotes (the insect form of the parasite) have been identified in some patient samples. Serologic tests, such as direct agglutination and indirect fluorescent assays, can be used to detect antibodies in individuals from nonendemic areas.

Trypanosoma

Trypanosomes are blood and CSF flagellates that require an insect vector. *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense* are the causative agents of human African trypanosomiasis, commonly called *sleeping sickness*, which is seen primarily in Central Africa. The tsetse fly (genus *Glossina*) serves as the insect vector. West African sleeping sickness, caused by *T. brucei gambiense*, is the more common, milder,

and more chronic of the two diseases. A long asymptomatic stage is followed by death years later. East African sleeping sickness, caused by *T. brucei rhodesiense*, is characterized by a rapid course, often resulting in death within 6 months after the onset of symptoms. East African sleeping sickness is a zoonosis, with game animals serving as important reservoirs of *T. brucei rhodesiense*. Humans are the main reservoir for *T. brucei gambiense*, but this species can sometimes be found in animals. *T. cruzi*, the agent of American trypanosomiasis or Chagas disease, is discussed in the next section.

Clinical infections

Initial symptoms of African sleeping sickness include a local inflammatory reaction with tenderness, edema, and erythema at the site of the insect bite. This occurs within 2 to 3 days and can last up to 4 weeks. During this time, the organisms are reproducing and beginning to enter the bloodstream. The first stage of the disease is the hemolymphatic phase, which occurs about 1 to 3 weeks after infection. Trypomastigotes enter the blood and lymphatics, and the patient experiences generalized symptoms, including fever, headache, joint and muscle pain, weakness, and lymphadenopathy. Enlargement of the lymph glands in the posterolateral triangle of the neck is known as the *Winterbottom sign*. Edema in the legs and arms and around the eyes is possible. While circulating, the organisms can resist antibody-mediated destruction as a result of continuous antigenic variation. A protective glycoprotein layer helps the organism resist direct lysis by complement. The second (meningoencephalitic) stage begins as the trypomastigotes invade the CNS; the patient develops severe headaches, mental dullness, and apathy, and may experience

Fig. 28.26 Life cycle of the agents of sleeping sickness (*Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*).

coordination problems, altered reflexes, and paralysis. Eventually, the patient has convulsions, lapses into a coma, and dies.

Life cycle

The tsetse fly is the biological vector for agents of sleeping sickness. Fig. 28.26 shows the generalized life cycle of these agents. The fly ingests the trypomastigote stage when it takes a blood meal from a human. The organisms migrate to the insect gut and multiply. The organisms later migrate back to the salivary gland where they transform into the epimastigote form. The epimastigotes multiply and develop into infective metacyclic trypomastigotes, which are transmitted to humans in saliva when the fly takes another blood meal. The trypomastigote form first circulates in the blood and lymphatic system, ultimately invading the CNS.

Laboratory diagnosis

The diagnostic stage in humans is the trypomastigote, which is usually seen in a Wright-stained blood smear, although wet films may be used to detect motile trypomastigotes. Blood concentration methods are often needed because of the small

number of organisms present. The organism can also be detected in lymphatic fluid and CSF. In infected individuals, CSF will often show increased numbers of WBCs (primarily lymphocytes) and elevated protein levels. The trypomastigote is 15 to 20 μm long, with a single large nucleus and a posterior kinetoplast to which is attached the flagellum of the undulating membrane (Fig. 28.27). *Trypanosoma* spp. cannot be differentiated on a blood smear; therefore the organism is reported as *Trypanosoma* sp. Final determination of species may be made on the basis of clinical symptoms and the geographic area.

The QBC method, which has been used in the detection of malarial parasites, has also been adapted for the detection of trypomastigotes. Field diagnosis of infection is important in endemic areas, and a serologic method using a card agglutination test for trypanosomiasis (CATT) and a micro-CATT have been developed. The test uses lyophilized *T. brucei gambiense* antigens to detect antibodies in blood. The test cannot distinguish current infection from past infection; therefore microscopy should be used to confirm the presence of the organisms in blood. It cannot be used as a test of cure because antibodies can persist for years after treatment. A latex agglutination test

Fig. 28.27 *Trypanosoma* trypomastigote in a blood smear. The anterior flagellum is not visible in this organism. (Giemsa stain, $\times 1000$.)

that uses three surface antigens is considered more specific than the CATT. There is no comparable method for detecting *T. brucei rhodesiense*.

Trypanosoma cruzi

Chagas disease is a zoonotic infection found primarily in rural areas of Mexico and Central and South America. It is caused by the hemoflagellate *T. cruzi*, transmitted by the triatomid bug, also known as the *reduviid* or *kissing bug* (*Triatoma* sp. or *Panstrongylus* sp.). It has been estimated that up to 20 million people in these regions are infected. Reduviid bugs live in the mud walls or thatch walls of a dwelling during the day and come out at night to take a blood meal from the human inhabitants. Some animals, such as armadillos and opossums, may also be infected by the organism and serve as reservoirs. Sporadic cases of infection have been reported among nonimmigrants in the United States because several of the insect vectors exist there.

Although insect transmission is most common, the organism has been transmitted via blood transfusion (especially platelet concentrate), transplanted organs, and congenital infection. In endemic areas of the world, transmission via transfusion is relatively common, and in North America, several cases of transfusion-transmitted Chagas disease have been reported. Donors in these cases were asymptomatic and in the latent or chronic state of the disease. There are estimates that greater than 300,000 immigrants living in the United States are chronically infected and could be capable of transmitting Chagas disease through transfusions or solid organ transplantations. Screening of blood donors for antibodies to *T. cruzi* in some countries of Central and South America has decreased the rate of transfusion-related transmission. Screening tests for blood donors in the United States have been implemented.

Clinical infections

Infections may be symptomatic or asymptomatic. The infection is divided into three phases: acute, intermediate (latent), and chronic. After the insect bites, there is an incubation period that ranges from 2 to 4 weeks. As the organisms enter the blood, the acute phase begins and lasts 4 to 8 weeks. Individuals in the acute phase may be asymptomatic or have local symptoms, including the presence of a *chagoma* (ulcerative skin lesion at the site of the insect bite) or unilateral

edema around the eye (Romaña sign) if the bite is near the ocular conjunctiva. Systemic manifestations include fever, lymphadenitis, hepatosplenomegaly, malaise, muscular pains, and diarrhea and vomiting. Adults often have a milder form of the disease, and the most severe form of acute infection usually occurs in children. This may manifest itself as myocarditis or meningoencephalitis. If untreated during the acute phase, the patient will most likely remain chronically infected.

The latent period develops as the trypomastigotes disappear from the circulation and invade the cells of the cardiac or GI system. The latent phase can last 10 to 40 years after infection, but only about 30% to 40% of patients develop the chronic form of Chagas disease—primarily cardiomyopathy. Chronic myocarditis develops with damage to all heart chambers and the conduction system. This may progress to tachycardia and eventually congestive heart failure. In some patients, the chronic form may manifest itself as megacolon, megastomach, or megaesophagus, which results in difficulty swallowing and disturbances to intestinal motility. Damage to the organs is caused by a combination of continuous low-level parasitemia and immune-mediated tissue damage, including high levels of TNF- α and IFN- γ . Polyclonal B-cell activation in the acute phase produces antibodies that have a weak affinity for the organism and may cross-react with heart tissue. Controversy exists about the role of these autoantibodies in tissue damage. When the patient enters the chronic stage of the disease, there are periods of intermittent parasitemia of trypomastigotes, during which time the organism may be transmitted.

Life cycle

Transmission of the organism to humans occurs when the insect vector defecates in the area surrounding its bite site. Metacyclic trypomastigotes in the feces are scratched into the bite site and invade the bloodstream. The trypomastigotes circulate in the bloodstream and eventually enter the cells, where they transform into amastigotes. Cells of the cardiac muscle and skeletal muscle are most commonly infected. Within the cell, the amastigote multiplies and causes the cell to rupture. Free amastigotes then invade other cells. A few of the released amastigotes will transform into trypomastigotes in the bloodstream and can be ingested by the insect to continue the life cycle. [Fig. 28.28](#) shows the life cycle of *T. cruzi*.

Laboratory diagnosis

The primary diagnostic stage in blood during acute infection is the trypomastigote. It is an elongated structure 15 to 20 μm long that often appears in a C or U shape. Like the other trypomastigotes, it shows a single, large-nucleus midbody; a single anterior flagellum; and a posterior kinetoplast to which the undulating membrane is attached. In most Wright-stained smears, the nucleus and kinetoplast and parts of the undulating membrane are well stained, but only the suggestion of a flagellum can be seen at the anterior end. In the chronic stage, the organism can be seen as an amastigote in a cardiac or other tissue biopsy specimen. The morphology of all trypomastigotes is similar (see [Fig. 28.27](#)); therefore the complete patient history must be obtained to determine the species present. If the history is not available, then the organisms are reported as trypomastigotes of *Trypanosoma* spp. Diagnosis of chronic infection with *T. cruzi* is based on patient history, clinical symptoms, and

Fig. 28.28 Life cycle of *Trypanosoma cruzi*.

presence of IgG antibodies to the organism. Serologic testing for antibodies to *T. cruzi* is also used in screening blood donors in the United States and other countries.

Xenodiagnosis is used in Central and South America as a diagnostic method. A laboratory-raised triatomid bug is allowed to feed on patients suspected of having *T. cruzi* infection. The insect's feces are examined on a regular basis for the presence of the parasite. Presence of the parasite in the insect's feces indicates that the patient was infected. This method is most helpful for diagnosing infections in the chronic stage, when fewer parasites are present. Rapid diagnostic tests (RDTs) using whole blood are under evaluation for testing individuals in remote areas.

Apicomplexa

The phylum Apicomplexa includes blood and tissue parasites. This group of organisms shows a diversity of morphology and transmission methods and can infect many different body sites. The life cycles are complex, characterized by sexual reproduction and **asexual reproduction** (reproduction when offspring arise from a single parent) phases. In addition, some may require an insect vector or intermediate host for completion of the life cycle. Humans can serve as **definitive hosts**

when **sexual reproduction** (offspring arise from the exchange of genetic material between two parents) occurs in human tissues and as intermediate hosts when asexual reproduction occurs.

Plasmodium

Plasmodium spp., which cause malaria, remain endemic throughout the world in tropical and subtropical countries, with almost one half of the world's population residing in an endemic area. *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium falciparum* are the causative agents of human malaria. A fifth species, *Plasmodium knowlesi*, which originated in simian species, is now associated with cases of human malaria and has been reported in most countries of Southeast Asia. Along with schistosomiasis and amebiasis, malaria is a major cause of death in people in underdeveloped countries. In 2020, there were an estimated 241 million cases worldwide with 627,000 deaths. The majority of infections occur in sub-Saharan Africa, where *P. falciparum* is the predominant species. Children under 5 years of age are the most at risk and accounted for 77% of malaria deaths in 2020. In the United States, approximately 2000 cases are reported annually, with *P. falciparum* being the causative agent in more

than 50% of cases. Most cases are seen in persons who have traveled to endemic areas.

P. vivax has the widest geographic distribution and is the species most likely to be found in temperate climates. *P. vivax* and *P. falciparum* cause more than 95% of infections. *P. ovale* is primarily confined to western parts of Africa; *P. falciparum* and *P. malariae* have similar distributions throughout Africa and in tropical countries. In general, infections caused by *P. vivax*, *P. ovale*, and *P. malariae* are less severe than those caused by *P. falciparum*.

Clinical infections

Although malaria is usually transmitted through the bite of an anopheline mosquito, transmission through blood transfusion and infected needles has been reported. Transplacental infection also has been documented. In these cases, the organism is sequestered in the placenta and can compromise fetal development because it affects transplacental transport of nutrients.

The malarial paroxysm, which begins 10 to 15 days after the bite of an infected mosquito, is associated with the growth of the parasites in RBCs and release of high levels of cytokines. Symptoms are linked to the rupture of RBCs and release of **merozoites** (parasitic forms produced from multiple fission), malarial metabolites, and endotoxin-like substances into the bloodstream.

The malarial paroxysm has three phases. The prodromal phase involves headache, bone pain, nausea, and/or flulike symptoms. In the first phase the patient experiences a shaking chill lasting 15 to 60 minutes. The second phase is characterized by a fever up to 40° C along with headache, myalgia, and nausea lasting 2 to 4 hours. In the third and final phase the fever finally breaks. Over the course of 2 to 4 hours, the patient begins to sweat profusely and is left exhausted and sleepy. This cycle repeats itself at regular intervals, depending on the species of malarial organism present, as parasites exit infected RBCs. The anemia seen in malaria is the result of lysis of erythrocytes, removal of the infected cells by splenic macrophages, and in some cases immune clearance of erythrocytes coated with immune complexes of malarial antigens and antibodies. In small children and in those with heavy infections, severe anemia can develop.

Long-term infection with any malarial organism may result in damage to the liver and spleen caused by deposits of malarial pigment (hemozoin). *P. vivax* and *P. ovale* infections generally do not have the range of complications seen with other species. Because the organism invades reticulocytes, there is generally low-level parasitemia (2% to 5%). However, the persistence of hypnozoites that remain dormant in the liver can lead to relapses within 3 years of initial exposure. *P. malariae* infections can lead to nephrotic syndrome, which arises from the deposition of circulating immune complexes of malarial antigens and antibodies on the basement membrane of the glomeruli, causing an autoimmune-like reaction. This organism has the most chronic course, and recrudescence occurs even decades after the initial infection.

The most severe form of malaria is caused by *P. falciparum*. Up to 50% of erythrocytes may be infected, and the primary complication is development of cerebral malaria. Between 20% and 50% of deaths caused by *P. falciparum* are the result of CNS complications. The parasite-infected RBCs demonstrate

sticky knobs that mediate adhesion to the endothelial cells of the capillary walls. The parasite protein *P. falciparum* erythrocyte membrane protein 1 is involved in mediating this attachment. In addition, complement receptor 1 on the surface of erythrocytes may help infected cells bind with other erythrocytes to form rosettes that can obstruct small capillaries. Blood flow is slowed in the microcirculation, reducing oxygen delivery to the tissues, with resultant tissue anoxia. The patient has severe headaches, may be confused, and ultimately lapses into a coma.

A second but less common complication of infection with *P. falciparum* is **blackwater fever**, a condition characterized by hemoglobinuria (hence the term *blackwater*). It usually develops in patients with repeated infections and those undergoing quinine therapy. Blackwater fever may be mediated by an antigen-antibody reaction caused by the development of an autoantibody to the RBCs. The black appearance of the urine is the result of massive intravascular hemolysis and resulting hemoglobinuria that appears black in acid urine. In addition, the high-level parasitemia that often accompanies *P. falciparum* infection can lead to anemia and deposits of malarial pigment in some organs, such as the spleen. Renal complications, such as nephrotic syndrome or even renal failure, can occur with *P. falciparum* infection as a result of tubular necrosis brought about by tissue anoxia.

Although complete immunity to malaria does not exist, individuals in endemic areas develop antibodies against the asexual stages and merozoites, which helps reduce the parasite load and severity of illness. Merozoite-specific antibodies may help block invasion of the RBCs or enhance opsonization and induce phagocytosis by macrophages. In addition, reports of antibodies directed against **sporozoites** and **gametes** (sexual reproductive cells that unite with another cell to form a zygote) indicate that these also may help reduce the rate of infection and the severity of illness. Patients with hemoglobinopathies, such as sickle cell disease, hemoglobin C disease, and glucose-6-phosphate dehydrogenase deficiency, are somewhat protected against severe malaria because the parasite cannot replicate or, in some cases, exist in these RBCs.

Treatment

Chloroquine remains the primary drug for prophylaxis and treatment of malaria. It is effective against all asexual stages of malarial organisms and all gametocytes, except those of *P. falciparum*. Many strains of *P. falciparum* have become resistant to the drug. Recent reports indicate that strains of *P. vivax* in Southeast Asia and Papua New Guinea also show diminished response to treatment with chloroquine.

P. falciparum has also demonstrated resistance to sulfadoxine-pyrimethamine (Fansidar) and mefloquine (Lariam) in parts of South America, Southeast Asia, and Africa. Doxycycline, atovaquone-proguanil (Malarone), or quinine use has been reestablished in some cases of multidrug-resistant *P. falciparum*. Chloroquine-resistant *P. vivax* may be treated with mefloquine or quinine sulfate with doxycycline. Primaquine phosphate, which is effective against hypnozoites that persist in the liver, is used to treat individuals infected with *P. vivax* and *P. ovale* to prevent relapses of these infections. There is also evidence that some strains of *P. vivax* in the geographic areas of chloroquine resistance may be refractory to primaquine. Artemisinin-based drugs have been used in

Fig. 28.29 Life cycle of *Plasmodium* spp.

combination with classic drugs in areas in which highly resistant strains of *P. falciparum* have emerged.

The level of parasitemia should be calculated as a percentage before and during treatment to follow effectiveness of treatment. In cases of high-level parasitemia, an RBC exchange may be used before treatment to decrease the level of parasitemia and increase effectiveness of the drug.

Life cycle

The life cycle of *Plasmodium* involves sexual reproduction (**sporogony**) and asexual reproduction (**schizogony**), as shown in Fig. 28.29. Sporogony is the formation of oocysts containing sporozoites that results from the division of a zygote. Schizogony produces merozoites by the process of multiple fission. The female *Anopheles* mosquito, in which sexual reproduction occurs, serves as the biological vector and definitive host. Asexual reproduction, which occurs in humans, has an **exoerythrocytic phase** that takes place in the liver and an **erythrocytic phase** that takes place in erythrocytes.

In human infections, the earliest stage is the ring-form trophozoite (Fig. 28.30), in which the organism has a prominent, red-to-purple chromatin dot and a small blue ring

of cytoplasm surrounding a vacuole (in a Giemsa-stained blood smear). The growing trophozoite is characterized by an increase in the amount of cytoplasm, the disappearance of the vacuole, and the appearance of malarial pigment in the organism's cytoplasm. The immature **schizont** (multinucleate stage) is characterized by a splitting of the chromatin mass. The mature schizont contains merozoites, which are individual chromatin masses, each surrounded by cytoplasm. Microgametocytes (male) have pale blue cytoplasm and a diffuse chromatin mass that stains pale pink to purple. The chromatin may be surrounded by a clear halo. Macrogametocytes (female) show a well-defined, compact chromatin mass that stains dark pink; the cytoplasm stains a darker blue than in microgametocytes. The chromatin mass often is set eccentrically in the organism. Pigment is distributed throughout the cytoplasm except in *P. falciparum*, in which it is often clumped near the chromatin mass.

Exoerythrocytic phase

Humans serve as intermediate hosts and acquire the infection when the female mosquito takes a blood meal and injects the infective sporozoites with salivary secretions. The sporozoites

Fig. 28.30 Life cycle stages of *Plasmodium* spp.

enter the human circulation and take approximately 60 minutes to reach the liver, where they begin the exoerythrocytic phase by penetrating parenchymal cells. Maturation through the trophozoite and schizont phases results in the production of hepatic merozoites. Each schizont produces a large number of merozoites. The release of mature merozoites from liver cells and invasion of RBCs signal the beginning of the erythrocytic phase. Generally, only one cycle of merozoite production occurs in the liver before RBCs are invaded. *P. vivax* and *P. ovale*, however, may persist in the liver in a dormant stage known as *hypnozoites*, which accounts for the relapse (recurrence) of the disease within 1 to 3 years after the primary infection. Neither *P. malariae* nor *P. falciparum* has a persistent liver phase, although recrudescence in untreated individuals with either of these organisms may be the result of a continued subclinical erythrocytic infection.

Erythrocytic phase

Merozoites have structures and proteins (e.g., erythrocyte-binding antigen) that selectively adhere to receptors on the RBC membrane. *P. vivax* and *P. knowlesi* use antigens of the Duffy blood group as receptors for attachment to and internalization into the RBCs, whereas *P. falciparum* may simply attach to receptors that are integral parts of the RBC membrane itself. Organisms may evade antibody recognition by varying their antigenic makeup. When merozoites have attached, endocytic invagination of the RBC membrane allows the organism to enter the RBC within a vacuole.

Once inside the RBC, the organism feeds on hemoglobin and initiates the erythrocytic phase. Malarial pigment, which

is composed of iron deposits, is formed in the growing trophozoite as a result of incomplete metabolism of hemoglobin. Once the organism has reached the mature trophozoite stage, the chromatin begins to divide (developing schizont). When the chromatin split has been completed (mature schizont), each chromatin mass is surrounded by its own small amount of malarial cytoplasm (merozoite). Each malarial species has a typical number of merozoites, which may be used as an identifying characteristic. When the RBC ruptures, merozoites are released to invade other RBCs. At this point, two outcomes are possible. One is that the merozoite enters a cell and repeats development into a schizont, and the other is that it enters a cell and develops into one of the sexual stages, the microgametocyte or macrogametocyte.

Sexual phase

Sporogony, which takes place in the mosquito, results in the production of sporozoites infective for humans. Both the microgametocyte and the macrogametocyte are infective for the female mosquito when she takes a blood meal. In the insect's stomach, exflagellation by the male microgamete and subsequent fertilization of the female macrogamete result in formation of an ookinete that migrates through the gut wall and forms an oocyst on the exterior gut wall. Sporozoites are produced within the oocyst. Mature sporozoites are released into the body cavity of the mosquito and migrate to the salivary glands. The female then injects sporozoites into a human as she takes her blood meal.

Laboratory diagnosis

History of travel to an endemic area and the presence of classic clinical symptoms, including the malarial paroxysm of fever and chills, should alert a health care provider to request Giemsa-stained thick and thin smears for malaria. Examination of these blood smears remains the classic method of diagnosing malaria. Laboratory identification of malarial species involves examination of the morphology of infected RBCs and characteristic morphology of the parasite. The thick smear is used to detect malarial parasites; however, distortions of parasite morphology and the lack of intact RBCs require that a thin smear be examined to identify the species. Trophozoites, schizonts, and gametocytes may be seen in the blood smear. It is recommended that at least 200 to 300 oil immersion fields be examined on either type of smear before the smear is considered negative. In addition, more than one set of smears should be made within a 36-hour period because one set is inadequate to completely rule out the presence of malarial organisms. Table 28.6 gives the general characteristics of trophozoites and schizonts of the human malarial species.

The QBC system using the fluorescent dye acridine orange is a sensitive method for demonstrating the presence of parasites; however, a thin smear must still be examined for definitive identification of *Plasmodium* spp. Nucleic acid amplification tests have been proposed as another method for diagnosing malaria. They have good sensitivity in detecting low levels of *P. falciparum* infection. However, the extended time and costly equipment required do not make the procedure cost-effective or efficient, especially for field work.

Several different immunoassays, collectively referred to as *RDTs*, use malarial antibody-impregnated dipsticks to

Table 28.6 Comparisons of malarial species

Plasmodium species	Red blood cell morphology	Trophozoite	No. of merozoites in schizont	Reproductive cycle (hours)	Other characteristics
<i>P. vivax</i>	Enlarged (to $\times 2$) Schüffner dots	Ameboid Large vacuoles Golden-brown pigment	12–24 Average: 16	48	Wide range of stages in peripheral blood
<i>P. malariae</i>	Normal size May have dark hue Ziemann dots (rare)	Compact May assume band form across cell Coarse, dark brown pigment	6–12; average, 8 with daisy petal-like arrangement around clumped pigment	72	Wide range of stages in peripheral blood
<i>P. ovale</i>	Enlarged, oval Fringed edge Schüffner dots	Compact Golden-brown pigment (resembles <i>P. vivax</i>)	6–14 Average: 8	48	Wide range of stages in peripheral blood
<i>P. falciparum</i>	Normal size Multiple infections	Small, delicate Double chromatin dots Appliqué forms Dark pigment	8–24 Average: 20–24	Irregular, 36–48	Crescent-shaped gametocyte Ring and gametocyte stages only in peripheral blood

detect *Plasmodium* infection. These use an antigen capture immunochromatographic principle to detect soluble proteins from malarial organisms in blood. Some tests use a monoclonal antibody directed against an antigen specific to *P. falciparum*, histidine-rich protein 2. Other tests use an antibody that detects a protein common to all species, parasite lactate dehydrogenase or *Plasmodium* aldolase. One commercial rapid detection kit is approved for use in the United States. Serologic tests for antibody to malaria are not useful in an endemic area but may be useful for diagnosis in those who have traveled to an endemic area and have clinical symptoms of malaria. Testing for the presence of hemozoin in blood is an emerging area of malaria diagnostics.

Plasmodium vivax

Plasmodium vivax has a *tertian* life cycle pattern; that is, it takes approximately 48 hours for the life cycle to be completed. The invasion of a new group of RBCs begins on the third day. *P. vivax* usually invades young RBCs (reticulocytes) and therefore is characterized by enlarged infected RBCs, often up to double the normal size. A fine pink stippling known as **Schüffner stippling** (or dots) may be present in the infected cell. The young trophozoite is characterized by its ameboid appearance; by maturity, it usually fills the RBC, and golden-brown malarial pigment is present. The mature schizont contains 12 to 24 merozoites, with an average of 16. Gametocytes are rounded and fill the cell. Macrogametocytes are often difficult to differentiate from mature trophozoites. Fig. 28.31 shows several stages of *P. vivax*.

Plasmodium malariae

Plasmodium malariae usually invades older RBCs, perhaps accounting for the occasional darker appearance of the invaded RBC. The life cycle is characterized as *quartan*, with reproduction occurring every 72 hours and invasion of new RBCs every fourth day. The trophozoite is compact and may assume a characteristic band appearance, in which it stretches across the diameter of the RBCs (Fig. 28.32A). Note the presence of dark, coarse, brown-to-black pigment in the band form. Occasionally, a few pink cytoplasmic dots, called

Ziemann dots, may be seen. The mature schizont contains 6 to 14 merozoites (see Fig. 28.32B), with an average of eight. Merozoites may be arranged in a characteristic “loose daisy petal” arrangement around the clumped pigment; however, they may also be randomly arranged.

Plasmodium ovale

Plasmodium ovale, the least commonly seen species, resembles *P. vivax*. In *P. ovale* infections, the RBC is enlarged and may assume an oval shape with fimbriated or fringelike edges. Schüffner dots are less commonly seen than with *P. vivax*. The parasite remains compact, has a golden-brown pigment, and has a range of 6 to 14 merozoites in the mature schizont. It also exhibits a tertian life cycle. Fig. 28.33A shows trophozoites of *P. ovale*. The Schüffner stippling in Fig. 28.33B has stained almost a bluish pink, but the compact organism and fimbriated cell are characteristic.

Plasmodium falciparum

Although identified as having a tertian life cycle, *P. falciparum* often demonstrates an asynchronous life cycle, with rupture of RBCs taking place at irregular intervals, ranging from 36 to 48 hours. The life cycle stages seen in peripheral blood are usually limited to the ring-form trophozoite and gametocyte. Other stages mature in the venules and capillaries of the major organs. *P. falciparum* invades RBCs of any age and, for this reason, often exhibits the highest level of parasitemia, reaching 50% in some cases. The ring forms of *P. falciparum* (Fig. 28.34A) are more delicate than those of other species and often have two chromatin dots. **Appliqué forms**, which are parasites at the edge of the RBC, and multiple ring forms in a single RBC are common. In this figure, the appliqué form is seen in the lower left and upper right of the photograph. Occasionally, small comma-shaped, red dots, referred to as **Maurer dots**, can be seen in the cytoplasm of infected cells. The mature trophozoite is small and compact and may have a dark brown pigment. The schizont (which is rarely seen in peripheral blood) has 8 to 24 merozoites, with an average of 20 to 24. Gametocytes have a characteristic banana or crescent shape (see Fig. 28.34B). *P. knowlesi* has early life cycle stages

Fig. 28.31 A, *Plasmodium vivax* trophozoite. B, *P. vivax* mature schizont. C, *P. vivax* macrogametocyte. D, *P. vivax* microgametocyte (Giemsa stain, $\times 1000$).

that resemble those of *P. falciparum* and mature trophozoites and gametocytes that resemble those of *P. malariae*. Therefore pertinent information, including travel history to an endemic area, is important in making a diagnosis.

Babesia spp.

Babesiosis is a zoonotic intraerythrocytic infection transmitted by the bite of a tick. *Babesia* spp. have been known to infect cattle and other vertebrates, but the first cases reported in humans occurred in the 1950s. These initial cases were limited to patients who had undergone splenectomy, but since then,

cases of babesiosis have been reported in patients who do not have asplenia. The hard tick (*Ixodes* spp.) serves as the vector, and white-footed mice and white-tailed deer are the reservoirs. There also have been reports indicating simultaneous transmission of *B. microti* and *Borrelia burgdorferi* (the causative agent of Lyme borreliosis) because these two organisms have the same tick vector. In the United States, most cases occur in the Northeast and upper Midwest. Patients often manifest clinical symptoms of one disease but show a concurrent increase and decrease in antibody titers to both *Babesia* spp. and *B. burgdorferi*.

There are over 100 species of *Babesia*, and several species have been reported to infect humans. *B. microti* in the United

Fig. 28.33 **A**, *Plasmodium ovale* trophozoite. The arrow denotes the fimbriated edge of the red blood cell. **B**, Schüffner stippling of *P. ovale* clearly visible (Giemsa stain, $\times 1000$).

States and *B. divergens* in Europe are the most common. Several cases of *Babesia duncani* and *B. duncani*-like organisms have been reported in areas from the state of Washington to California. Sporadic cases in the states of Missouri, Kentucky, and Washington occurred with an organism that more closely resembles *Babesia divergens*, a parasite of cattle in Europe. As with malaria, cases of congenital babesiosis have been reported.

The incidence of babesiosis in the United States increased from 1,761 cases in 2013 to 2,418 in 2019. The disease is a potential threat to the U.S. blood supply. *B. microti* is the most common parasite transmitted in transfused blood. There were 159 cases of transfusion-transmitted babesiosis reported between 1979 and 2009, with 122 cases (77%) occurring between 2000 and 2009. Through 2014, the number increased to over 200 transfusion-transmitted cases. Most cases were linked to RBC components. Currently, there are no FDA-approved tests for screening donor blood units for antibodies to *Babesia* spp.

Clinical infections

Most cases of babesiosis occur from May to September, when outdoor activities peak and exposure to ticks is highest. Infection is often asymptomatic, but the very young, older adults, and immunosuppressed patients are at greatest risk of symptomatic infection. Symptoms are related to the asexual reproductive cycle, lysis of RBCs, and the level of parasitemia. The time from infection to development of

symptoms is 1 to 6 weeks. Patients with babesiosis may have malaria-like symptoms, such as malaise, fever, chills, sweating, and myalgia; however, many patients are asymptomatic. The fever is not cyclic as in malaria. Anemia may develop if hemolysis is severe or prolonged. The clinical course tends to be more severe or have complications if the patient has undergone splenectomy, is immunosuppressed, or is older. Complications may include respiratory, liver, or renal failure or disseminated intravascular coagulation. Treatment includes atovaquone plus azithromycin or clindamycin plus quinine. In very severe infections, exchange transfusion may be used.

Life cycle

As with *Plasmodium* spp., the life cycle of *Babesia* spp. has alternating sexual and asexual reproduction stages. Production of the infective stage (sexual reproduction) takes place in the tick. The zygote migrates to the salivary glands of the tick, where sporozoites are formed. These sporozoites enter vertebrates during a blood meal and infect erythrocytes by attaching to a sialoglycoprotein on the erythrocyte membrane. Inside the cell, they become trophozoites and divide by asexual reproduction (budding) to form pairs and tetrads. Unlike malaria, in which the reproductive life cycle in the RBC may take 48 to 72 hours, the reproduction time in *Babesia* infection is approximately 4 to 6 hours. The resulting merozoites are released to infect other RBCs, where they use merozoite

surface proteins to attach to glycophorin A and glycophorin B on the RBC membrane. Some merozoites differentiate into gametocytes (larger, more variably shaped), but this is not an easily identifiable stage from the trophozoite. One difference in this life cycle from that of malaria is the absence of the exoerythrocytic cycle in humans. Transovarian transmission can occur in the tick, allowing the life cycle to persist without an intermediate host.

Laboratory diagnosis

The diagnosis of babesiosis is made from Wright- or Giemsa-stained thin blood smears. The organisms appear as small, delicate, pleomorphic ring-form trophozoites, about 1 to 2 μm in length, with a prominent chromatin dot and faintly staining cytoplasm. More mature trophozoites may appear as pyriform organisms in single, double, or the classic tetrad (Maltese cross) formation within the RBC. Fig. 28.35A shows several small, compact, ringlike trophozoites of *B. microti*; Fig. 28.35B demonstrates the irregularly arranged tetrad formation characteristic of the organism. Although they are characteristic for babesiosis, the tetrad forms are not always seen. Fig. 28.35C demonstrates a cell with a pair of trophozoites as well as cells with single organisms. The morphology initially may be confused with that of *P. falciparum*. Lack of pigment, presence of extraerythrocytic organisms, and absence of other life cycle stages serve as keys to differentiate *Babesia* from *P. falciparum*.

Patients with a normocytic hemolytic anemia may have decreased haptoglobin and elevated indirect bilirubin levels and reticulocytosis. Some patients may demonstrate elevated levels of liver enzymes and lactate dehydrogenase, and decreased numbers of platelets.

Serologic studies, such as immunofluorescence assays, can be used to detect circulating antibodies (IgM and IgG). The levels of IgM antibodies are usually elevated during the first 2 weeks and then decline. IgG titers greater than 1:1024 are generally considered indicative of recent or active infection. Although transfusion-transmitted babesiosis has been reported, there is no screening test for blood donors; obtaining a detailed donor history is the only method used to screen donors. Molecular methods to detect parasite DNA have been developed and may be used when there is a high suspicion of babesiosis but the smears remain negative.

Toxoplasma gondii

T. gondii is an obligate intracellular parasite found in mammals worldwide. Serologic studies have indicated that the rate of infection often differs among counties, but, overall, up to one third of individuals worldwide may be infected. More than 20% of the U.S. population shows serologic evidence of infection, but in parts of Europe, the proportion may be as high as 80%. Toxoplasmosis can present with a wide range of

Fig. 28.35 A, *Babesia microti* trophozoites (Giemsa stain). B, *B. microti* tetrad form identified by the arrow (Giemsa stain, $\times 1000$). C, Paired trophozoites and single trophozoites identified by arrows.

clinical symptoms and complications that are often related to the immunologic status of the patient. Most immunocompetent individuals do not have serious infection, whereas HIV-positive individuals, transplant recipients, and those with defects in T cell-mediated immunity are found to have the most serious forms of infection. In addition, infants may contract the disease in utero and present with various degrees of severity.

Clinical infections

The clinical presentation of toxoplasmosis differs based on the immunologic status of the individual. Immunocompetent patients with acute infections may be asymptomatic or may have mild flulike or mononucleosis-like symptoms, including low-grade fever, lymphadenopathy, malaise, and muscle pain. Once the acute infection has resolved, the organism enters a relatively inactive stage, in which tissue cysts containing many slow-growing forms of the organism are found.

The organism may also be transmitted congenitally because of a transient parasitemia in pregnant women who have primary infection. Congenital transmission occurs when the **tachyzoites**, the motile, rapidly dividing forms in maternal circulation, cross the placenta and enter fetal circulation and tissues. Children with congenital toxoplasmosis may have a range of serious complications, including intellectual disability, microcephaly, seizures, hydrocephalus, retinochoroiditis, and blindness. If the fetus is exposed to the infection early in the pregnancy, more severe complications are likely to result. Infections acquired later in pregnancy may result in the child being asymptomatic at birth but developing complications, especially ocular problems, later in childhood.

Immunosuppressed patients, particularly those with leukemia or lymphoma and those undergoing chemotherapy, may experience a serious primary infection or reactivation of a latent infection that can manifest itself as a fulminating encephalitis and result in rapid death. Up to 10% of the deaths of patients with AIDS are caused by reactivation of latent toxoplasmosis, resulting in encephalitis. Computed tomography (CT) may demonstrate lesions in the brain that represent *Toxoplasma* spp. cysts. Pulmonary toxoplasmosis may be present in conjunction with CNS infections or can be the presenting condition; however, the organism can spread to any organ of the body.

The organism can also be transmitted via organ transplantation. In this case, the organ may contain **bradyzoites**, which are slow-growing encysted forms of the parasite responsible for chronic infections that are reactivated in the immunocompromised recipient. This frequently occurs when the organ recipient is seronegative for *T. gondii* (lacks antibodies to *T. gondii*) and the organ donor is seropositive. In these patients, the infection usually occurs within the first 3 months after transplantation and may spread to multiple organs. In the case of a seropositive transplant recipient, immunosuppressive treatment to prevent organ rejection may reactivate a latent infection in the transplant recipient.

In general, toxoplasmosis in the immunocompetent host is not treated. When treatment is necessary, a combination of antimicrobials, such as trimethoprim-sulfamethoxazole, is used for treating the infection in the tachyzoite stage. The drugs are not effective against bradyzoites in cysts located in muscle and brain tissues.

Life cycle

T. gondii has two life-cycle stages in humans: tachyzoite and bradyzoite. Tachyzoites can invade any nucleated cell and are the actively motile and reproducing forms. They are crescent shaped, are 4 to 6 μm long, and have a prominent nucleus (Fig. 28.36A). Fig. 28.36B shows lung tissue containing free tachyzoites and a number of intracellular forms. Bradyzoites are the slow-growing asexual forms found in a cystlike structure during the dormant phase of infection.

As shown in the life cycle illustrated in Fig. 28.37, humans can acquire *T. gondii* infection in several ways, such as through ingestion or inhalation of the oocyst from cat feces, soil, or water; through ingestion of undercooked meat containing the cystlike structure with bradyzoites; and through congenital transmission. Primary risk factors for acquiring the infection include cleaning a cat litter box, gardening without gloves, and eating raw or undercooked meat or unwashed vegetables and fruit. The household cat and other members of the family Felidae serve as definitive hosts for the organism. Sexual and asexual reproduction occur in the intestine of the cat, whereas only asexual reproduction occurs in humans and other intermediate hosts. The result of sexual reproduction is the production of an oocyst, which is passed in cat feces. The oocyst requires 2 to 5 days in the environment to mature and become infective.

Fig. 28.36 A, *Toxoplasma gondii* tachyzoites, identified by the arrow (hematoxylin and eosin stain). B, *T. gondii* tachyzoites in lung tissue (hematoxylin and eosin stain, $\times 1000$).

Fig. 28.37 Life cycle of *Toxoplasma gondii*.

When a human ingests the infective oocyst, changes in pH and temperature induce release of sporozoites in the oocyst into the intestine. The sporozoites penetrate the intestinal wall, gain access to the circulation, and migrate to the organs. Migration of dendritic cells infected with tachyzoites is one of several proposed methods that contribute to dissemination. These *tachyzoites*, as they are now called, are responsible for tissue destruction. They invade cells by attaching to surface proteins (using receptors, such as proteoglycans) on nucleated cells, replicate intracellularly within a parasitophorous vacuole formed by the host cell plasma membrane, cause cells to rupture, and release tachyzoites to invade other cells.

The immune system, in particular, T cells, responds strongly when tachyzoites invade the tissues. This TH1 immune response includes the production of IL-12 and IFN- γ . Natural killer (NK) cells may also play a role in control of the organism. As a result of this immune response, tachyzoites are converted to bradyzoites, and eventually the cystlike structure contains hundreds to thousands of the slowly growing and reproducing bradyzoites. At this point, the infection generally remains dormant for the life of the host unless the immune system is compromised. In the immunocompromised patient, the bradyzoites are reactivated and released from the cyst and become active tachyzoites that invade multiple organs, resulting in disseminated infection.

If a human ingests raw or undercooked meat containing the tissue cysts, the cyst wall is dissolved and bradyzoites are liberated. These organisms are resistant to digestive tract

enzymes for about 6 hours, during which time they convert to tachyzoites and invade the intestinal wall. They then gain access to the circulation. All types of meat, including lamb, pork, beef, and that of game animals, such as deer and bear, have been implicated in this mechanism.

Laboratory diagnosis

Identification of the tachyzoite or pseudocysts with bradyzoites in tissue is very difficult because no single organ is invaded. Finding free tachyzoites in CSF, bronchoalveolar lavage specimens (Figs. 28.38 and 28.39), or specimens from other sites, such as lymph nodes, is unusual unless the infection is disseminated. In disseminated toxoplasmosis, histologic stains of biopsy materials may demonstrate the cyst or, in some cases, tachyzoites. Noninvasive techniques, such as magnetic resonance imaging (MRI) and CT, may be used in the diagnosis for patients suspected of having disseminated toxoplasmosis.

The levels of antibodies to the organism show a rapid increase during infection, and tests for antibodies are most commonly used for diagnosis. Indirect fluorescent antibody tests and EIAs with *T. gondii* organisms as the antigen are routinely used for diagnosis. Because most patients have an antibody titer to the organism, interpretation of the titer must be linked to clinical symptoms and the patient's history. A significant rise in titer (fourfold) between acute-phase and convalescent specimens may indicate acute infection. An IgM-specific test may also be used to diagnose acute infections and can be useful in the diagnosis of primary toxoplasmosis

Fig. 28.38 Bronchoalveolar lavage cytocentrifuge preparation, Wright-Giemsa stain, Crescent-shaped cells with central nucleus (arrows). Morphology consistent with trophozoites (tachyzoites) of *Toxoplasma gondii* (see Fig. 28.39).

in pregnant women suspected of having been exposed to the organism or in neonates in whom congenital infection is suspected. IgM titers usually peak within the first month of infection. Antibody titers may be unreliable in immunocompromised patients because these patients lack the ability to produce sufficient antibody to cause a significant increase in titer. PCR assays to detect *T. gondii* DNA may be used for CSF or amniotic fluid and are useful in detecting congenital infection in utero. Molecular methods are also used in bone marrow transplant recipients to detect infection.

Opportunistic intestinal Apicomplexa species

Cryptosporidium spp. are recognized for causing self-limiting GI infection in immunocompetent hosts. However, they have also been identified as opportunistic pathogens causing severe infection in immunocompromised hosts, particularly in those with AIDS. *Cryptosporidium* spp. are obligate intracellular parasites transmitted by ingestion of the infective oocyst. These organisms are transmitted by the fecal-oral route—ingestion of contaminated water or food or, for some, by direct contact with fecal material containing oocysts. The oocysts are infective at a low dose (as few as 10 oocysts) and are resistant to common chlorine- and ammonia-based disinfectants. Most infections are reported in summer, when there is increased recreational water activity. Foodborne infections

have been associated with ingestion of raw foods or unpasteurized drinks.

Sexual and asexual reproduction occur in the human intestinal tract. Over 30 *Cryptosporidium* species are recognized; *Cryptosporidium* was initially identified as causing zoonotic infections in veterinarians and other animal handlers. The parasites can infect a range of hosts including mammals, birds, and reptiles. Cows are an important reservoir for human disease. Now, over 20 species have been found in humans; the most common are *Cryptosporidium hominis* and *Cryptosporidium parvum*. Cryptosporidiosis is the leading cause of waterborne disease outbreaks in the United States. Outbreaks in daycare centers and from environmental contamination of municipal water supplies have been reported. In the 1980s, cryptosporidiosis was identified as a major opportunistic infection in patients with AIDS and classified as an AIDS-defining illness. In a 2019 report, the CDC estimated that 823,000 cases of cryptosporidiosis occur annually.

Clinical infections

In immunocompetent patients, the organisms cause a transient profuse, watery diarrhea along with mild to severe nausea and vomiting, headache, and cramps. The mucosa is inflamed, and there is an influx of segmented neutrophils, macrophages, and lymphocytes. The onset is rapid (within 3 to 7 days after ingestion of the oocyst), but the infection is self-limiting. Symptoms resolve in several weeks, although infections can last up to 1 month. Infection begins in the small intestine but may spread to the large intestine. In endemic areas, the first infection occurs in early childhood and is symptomatic with profuse, watery diarrhea, but subsequent infections are mild to asymptomatic. Antibodies (IgG, IgA, and IgM) are produced, but it is not clear how much of a protective role they play. Antibodies developed against one of the organisms can provide protection against infection by the same species, but antibodies developed against one species may provide only incomplete protection against another species. In addition, the host mounts a cell-mediated immune response (T cells and NK cells) that includes production of several cytokines, including IFN- γ and IL-12.

The organism alters osmotic pressure in the gut, with a resulting influx of fluid. The diarrhea is cholera-like, with bits of mucus and little fecal material. Fluid loss has been reported to range from 3 to 6 L/day to as much as 17 L/day. In addition to weight loss, patients show signs of dehydration and electrolyte imbalance. In patients with AIDS whose cell-mediated immunity is compromised and whose CD4 count is less than 50 cells/ μ L, the infection is more likely to become fulminant or life-threatening or spread to extraintestinal sites.

In chronic cases, the intestinal villi may show signs of atrophy caused by inflammation, and the brush border of the cells is disrupted because of invasion by the organism. This damage alters intestinal permeability and can result in decreased uptake of fluids, electrolytes, and nutrients. Malabsorption syndrome may occur. No antimicrobial is completely effective against this infection. Paromomycin and azithromycin, which can suppress the infection, have been used, with mixed results. Nitazoxanide, a relatively new agent, has been used for treating *Giardia* and *Cryptosporidium* infections in immunocompetent children and adults. It shortens the duration of diarrheal episodes and appears to be the only one of the drugs tested that has even partial effectiveness in immunocompromised individuals.

Life cycle

The sexual and asexual life cycles of *Cryptosporidium* occur in the same host. Life cycle stages, as shown in Fig. 28.40, develop under the brush border of the intestinal mucosal epithelial cells. Oocysts are infective when passed and may be ingested in contaminated water or food or passed by person-to-person contact. Ingestion of the infective oocyst initiates the asexual cycle (sporogony) with the release of sporozoites. Sporozoites attach to receptors on the intestinal mucosal border, penetrate an intestinal epithelial cell and create a parasitophorous vacuole between the cell membrane and cytoplasm, and mature into trophozoites in this intracellular but extracytoplasmic location. Once trophozoites have matured, the development of meronts with merozoites begins. The nucleus and cytoplasm divide to form individual organisms known as *merozoites*. When the meront ruptures, merozoites are released and penetrate other cells to continue asexual reproduction or to transform

into a microgamete or macrogamete. Fertilization of the macrogamete results in formation of the oocyst, which contains four sporozoites. Two types of oocysts may be formed, the thin-walled oocyst, which ruptures within the intestine and results in autoinfection, and the thick-walled, fully sporulated oocyst, which is infective when passed in feces. Key factors in the life cycle of this organism that contribute to its pathogenicity include the following:

- The oocysts are infective when passed in feces.
- Rupture of thin-walled oocysts in the intestine creates the potential for continual autoinfection.
- Patients may remain infective and continue to shed oocysts for a time after the diarrhea ceases.

Laboratory diagnosis

The small size (4 to 6 μm), refractile appearance, and round shape of the oocyst make detection difficult with routine

Fig. 28.40 Life cycle of *Cryptosporidium* sp.

concentration procedures because the organism may resemble a yeast or an RBC. More oocysts are seen in liquid stool than in formed stool. Trichrome and iron hematoxylin stains are not useful permanent stains for identification of *Cryptosporidium* spp. The recommended detection methods for *Cryptosporidium* infection are the modified acid-fast stain, an antigen detection test, and a DFA test using a monoclonal antibody directed against *Cryptosporidium* spp. These methods do not distinguish the species. With the acid-fast stain, the organism appears as a bright red sphere, which distinguishes it from yeasts, which stain green. Figs. 28.41, 28.42, and 28.43 show *Cryptosporidium* oocysts stained with modified acid-fast stain.

Studies indicate that antigen detection by monoclonal antibody tests demonstrates greater sensitivity and specificity than the modified acid-fast stain. EIA methods can also be used but are less sensitive (sensitivity of 70%) than fluorescent antibody methods. More recently, lateral-flow immunochromatographic assays have become available. These assays are highly specific (>99%), but the sensitivity ranges from 68% to 100%. Antigen-detection methods have become popular in clinical laboratories for their ease of use—they do not require an experienced microscopist.

Cystoisospora belli

Cystoisospora belli (formerly *Isospora belli*) is an opportunistic organism seen less frequently than *Cryptosporidium* spp. It is

Fig. 28.41 *Cryptosporidium* oocysts (modified acid-fast stain, $\times 1000$).

Fig. 28.42 Watery, frothy diarrheic stool, smear, acid-fast stain, ($\times 1000$). Acid-fast oocysts (4 to 6 μm). Sporulated oocysts containing four sporozoites (arrow). Morphology consistent with *Cryptosporidium* sp.

known to infect only humans. Most patients infected with *C. belli* are asymptomatic, but symptoms, such as low-grade fever, headache, diarrhea, and colicky abdominal pain, may be present. Acute infections with *C. belli* are usually clinically indistinguishable from those with *Cryptosporidium* spp. The infection is self-limiting and usually resolves in several weeks in an immunocompetent host. The infection is often more serious in immunocompromised patients, including those with AIDS and those with conditions such as Hodgkin disease, lymphoproliferative disorders, or lymphoblastic leukemia. These patients may have watery diarrhea and concurrent weight loss, or chronic infection may develop. Treatment with trimethoprim-sulfamethoxazole has been effective in eliminating diarrhea, but patients often show recurrence of infection when therapy is discontinued.

The life cycle of *C. belli* is similar to that of *Cryptosporidium* spp. in that it requires only one host but occurs within the cytoplasm of epithelial cells of the small intestine. The oocyst of this organism is not infective when passed in the feces and requires 24 to 48 hours outside the body to become infective. There is no thin-walled oocyst to cause continued autoinfection. The mature oocyst of *C. belli* is oval, 20 to 33 μm by 10 to 19 μm , with a hyaline cell wall. The immature oocyst usually shows a single **sporoblast** (an early stage in the development of a sporocyst, before differentiation of the sporozoites). The mature oocyst has two **sporocysts**, which are walled bodies. Each sporocyst contains four elongated sporozoites. Oocysts can be seen in wet mounts.

The modified acid-fast stain has been used to detect *C. belli*. The oocyst wall does not stain but often shows a faint outline because of precipitated stain, and the sporoblasts or sporocysts stain dark red. Like oocysts of *Cyclospora cayetanensis*, the oocysts of *C. belli* will autofluoresce a bluish color at 330 to 365 nm and a bright green at 450 to 490 nm. The size and shape of the oocyst serve as the identification characteristics. Fig. 28.44 shows the characteristic appearance of an acid-fast stain of the oocyst of *C. belli*.

Cyclospora cayetanensis

C. cayetanensis is a foodborne and waterborne organism causing endemic and epidemic diarrheal disease. Humans are the only known host for this organism, but other *Cyclospora* spp. are found in animals. The organism was first linked to human

Fig. 28.43 Watery, frothy diarrheic stool, smear, acid-fast stain. Acid-fast oocysts (4 to 6 μm) (arrows) ($\times 1000$). The measurement is taken to differentiate this oocyst from the 8- to 10- μm oocysts of *Cyclospora* spp. (see Fig. 28.45B).

Fig. 28.44 *Cycloispora belli* oocysts (modified acid-fast stain, $\times 1000$).

disease in the 1990s, when it was found in stool specimens. It was originally thought to be a *Cyanobacterium*-like body, blue-green alga, or large *C. parvum*.

C. cayetanensis is endemic in Nepal, Peru, Guatemala, and Haiti, but outbreaks have been reported in many countries, including those in Central and South America, parts of the Caribbean, India, and Europe. The usual mode of transmission is ingestion of fecally contaminated water or food. Most outbreaks in endemic areas occur during the rainy season. Persons living in these areas may acquire some level of immunity that increases resistance to future infection. Individuals who travel to endemic areas are susceptible to traveler's diarrhea caused by *C. cayetanensis*. The organism has also been linked to several large foodborne outbreaks in North America. Most of the outbreaks were associated with the consumption of contaminated imported fresh produce, especially raspberries and strawberries from endemic areas of Central America. Subsequently, there have been isolated outbreaks associated with imported vegetables, such as mesclun lettuce, basil, and snow peas. The infective dose is not known, but it is thought to be relatively low, between 10 and 100 oocysts.

Although the organism is most commonly encountered in immunocompetent patients, it may be considered an opportunistic infection in patients with AIDS. Symptoms of infection with *C. cayetanensis* differ based on age, infective dose, and host immune status. The incubation period is approximately 1 week. The organism infects cells in the upper portion of the small intestine and causes frequent, watery, but nonbloody stools that may alternate with bouts of constipation. Symptoms, which can mimic those of cryptosporidiosis or cystoisosporiasis, include anorexia, fatigue, weight loss, abdominal cramping and bloating, vomiting, low-grade fever, and nausea. Patients often report a flulike syndrome before the onset of diarrhea. In immunocompetent hosts, the symptoms are self-limiting and persist for several weeks but may occur in a relapsing pattern for up to 2 months.

Immunocompromised patients have prolonged course and can be symptomatic for as long as 4 months. Some cases of malabsorption caused by inflammation and damage to the intestinal villi and a few cases of extraintestinal infection have occurred in immunocompromised patients. In endemic areas, infections are common in children 2 to 10 years of age, and most infections resolve spontaneously. Trimethoprim-sulfamethoxazole is used to treat the infection; when treatment is started, symptoms usually abate within several days.

Fig. 28.45 *Cyclospora cayetanensis* oocyst. **A**, Wet mount. **B**, Modified acid-fast stain. (**A**, original magnification $\times 1000$; **B**, $\times 1000$.)

The organism shares the general life cycle characteristics of other intestinal Apicomplexa species. Once the mature oocyst has been ingested, the presence of bile and trypsin in the small intestine helps trigger release of sporozoites, which invade the intestinal cells. Two types of meronts develop: type I, which produce merozoites that infect other intestinal cells (asexual cycle), and type II, which progress to the sexual stage. Once fertilization occurs, a zygote forms and develops into an immature oocyst that is passed in feces. Unlike *Cryptosporidium*, however, immediate person-to-person transmission is unusual because these oocysts require about 1 to 2 weeks outside the body to mature and become infective.

The oocyst is similar to that of human *Cryptosporidium* spp. but larger, with an average size of 8 to 10 μm . In wet mounts, the oocyst appears nonrefractile, spherical, and unsporulated, with multiple internal globules or granules. Sporulation occurs after several days, resulting in the production of two sporocysts with two sporozoites each. The organism does not stain with traditional trichrome or iron hematoxylin stains. The modified acid-fast stain demonstrates variably staining organisms, from dark pink to almost colorless (ghost forms), with no visible internal structures. Fig. 28.45A shows an oocyst of *C. cayetanensis* in a wet mount, and Fig. 28.45B shows an oocyst in an acid-fast stain. For comparison, Fig. 28.43 shows acid-fast *Cryptosporidium* oocysts that measure 4 to 6 μm (arrows).

One distinguishing characteristic of *C. cayetanensis* is autofluorescence, exhibiting a bright blue fluorescence (330 to 365 nm) or mint green fluorescence (450 to 490 nm) under ultraviolet light. Nucleic acid detection methods developed in reference and research laboratories are often used for

identification during outbreaks. Serologic methods to detect antibodies and antigen detection assays are not available.

Microsporidia

In the mid-1980s, a group of organisms were linked to infections in patients with HIV infection. These organisms, collectively referred to as *microsporidia*, are obligate intracellular, parasites common to invertebrates and other animals. Originally considered protists, they have been reclassified as fungi based on chitin present in the spore wall and rRNA sequencing. There are more than 200 genera and 1500 species identified, with many being reclassified based on molecular sequencing. At least nine genera (*Anncaliia*, *Encephalitozoon*, *Endoreticulatus*, *Enterocytozoon*, *Nosema*, *Pleistophora*, *Trachipleistophora*, *Tubulinosema*, *Vittaforma*, and the unclassified collective group *Microsporidium*) have been implicated in human infections. Although infection with the organisms is often linked to HIV infection, microsporidia have been identified in organ transplant recipients, older adults, and patients with traveler's diarrhea. The organisms are capable of infecting a wide variety of human organs, including intestine, eyes, muscles, liver, kidneys, and CNS.

Clinical infections

Symptoms differ with the species and organ infected. Intestinal infections are most often caused by *Enterocytozoon bieneusi* or *Encephalitozoon intestinalis*, and infection in immunocompetent hosts is characterized by diarrhea, cramps, loss of appetite, and fatigue. Dehydration and weight loss are sometimes seen. Infected patients have four to eight liquid or loose stools a day, and symptoms may persist for up to 8 months, with spontaneous exacerbations and remissions. In patients with AIDS, infection is chronic, and the diarrhea may persist for several years, with malabsorption of fats and vitamin B₁₂ and cachexia as additional complications. Risk factors in patients with AIDS include sexual transmission, a CD4 cell count of less than 100/ μ L, exposure to water during swimming, and contact with animals. Dissemination of *E. intestinalis*, especially to the urinary tract, gallbladder, or respiratory tract, has been seen. Dissemination to muscles may result in weakness and pain. Patients with AIDS can develop encephalitis, nephritis, or keratoconjunctivitis. Contact lens wear is a risk factor for corneal infection. Albendazole has been used to treat infections with *Encephalitozoon* spp., but most other microsporidial organisms are resistant to this and other drugs. Metronidazole may provide some relief, but the symptoms recur when use of the drug is discontinued. Disseminated infections have also been reported.

Life cycle

The infective stage for humans is the environmentally resistant spore, which can survive outside the host for as long as 1 year. Once the infective spore is ingested, shifts in pH and ionic concentration in the intestinal tract trigger infection. The organism gains access to host cells by emergence of a polar tube through the spore wall and its insertion through the cell membrane. This insertion is thought to be mediated by a series of molecular interactions between the tip of the

polar tube and receptors on the cell membrane. The contents of the spore (sporoplasm containing a nucleus, ribosomes, Golgi apparatus) are then transferred into the cell. Within the host cell, the sporoplasm divides and develops into meronts. These structures subsequently develop into sporoblasts that differentiate into sporonts. As these structures mature into spores, they develop a thick membrane and the polar tube. The host cell ruptures, and spores are released to penetrate other host cells to repeat the reproductive cycle or be passed from the body. In the case of intestinal infection, spores are passed in feces; in infection of the urinary tract, they can be detected in urine.

Laboratory diagnosis

Microsporidia can be found in stool, bronchoalveolar lavage fluid, sputum, CSF, conjunctival swabs, corneal scrapings, and other specimens. Initially, identification methods were limited to finding the small spores in Giemsa-stained tissue sections or in electron microscopic examination of biopsy specimens. Electron microscopy must be used to identify the species of the organism. Speciation is based on the number of coils in the polar tubule, septations in the spore, and size.

Routine O & P examination will not detect the spores in a fecal specimen. However, staining of formalin-preserved feces using the Weber modification of the trichrome stain and the Ryan trichrome blue stain can be used to detect microsporidial spores. The small size of the spores, however, makes them easy to overlook in clinical specimens. A thin smear of feces must be used so debris does not obscure the small, faintly staining spores. Fig. 28.46 shows the small spores (1.5 to 4.0 μ m) in a chromotrope stain of a fecal specimen. Spores stain pink to red and may have a diagonal or equatorial band that helps distinguish them from bacteria or yeasts. Background staining in the Weber stain is pale green (Fig. 28.47), whereas in the Ryan stain it is blue. A Gram-chromotrope stain will produce spores that are dark violet and demonstrate an equatorial band.

Calcofluor white, a fluorescent stain used for the detection of fungi, can also be used to screen specimens for microsporidial spores. The stain is a chemofluorescent agent, such as the Remel Calcofluor White Stain Kit (Thermo Fisher Scientific, Waltham, MA) or Fungi-Fluor (Polysciences, Warrington, PA).

Fig. 28.46 Microsporidia spores identified by the arrow (chromotrope stain, $\times 1000$). (Courtesy Texas Department of State Health, Austin, TX.)

Fig. 28.47 Diarrheic stool, smear, modified Weber stain, light microscopy, $\times 2000$ oil. Parasite spores, small ($1.5 \times 0.9 \mu\text{m}$). Morphology consistent with *Enterocytozoon* sp. (arrow 1) (see Fig. 28.48). Compare with size of the yeast (arrow 2).

Fig. 28.48 Diarrheic stool from concentration, transmission electron microscopy, $\times 57,000$. Endospore layer and polar tubes are present. Morphology is consistent with *Enterocytozoon bieneusi*.

The stain is nonspecific and binds to chitin in the spore wall. Therefore the presence of spores should be confirmed by using one of the modified trichrome stains. Species-specific indirect fluorescent antibody staining is useful to identify spores in fluids, such as urine, or in biopsy specimens. Species-specific PCR assays are also available for identification. The transmission electron microscope micrograph in Fig. 28.48 shows an endospore layer and polar tubes. The morphology is consistent with *Enterocytozoon bieneusi*.

Helminths

Helminth infections in humans are caused by flukes, tapeworms, or roundworms. Humans become infected by directly ingesting eggs (ova), by ingesting larvae in an intermediate host, or through direct larval penetration of the skin. Adult forms do not multiply in the human body; therefore the number of adult worms present is related to the number of eggs or larvae ingested. The pathologic consequences and severity of infection are related to the number of adults

present, commonly referred to as the *worm burden*. Patients with only a few adult worms are usually asymptomatic, whereas a patient with a large number of adults often shows clinical symptoms. Most of the parasites inhabit the intestinal tract, but species also infect the liver, lungs, lymphatics, and blood vessels.

Flukes

Flukes (trematodes) are members of the phylum Platyhelminthes, or flatworms. Most infections are seen in people from East Asia, Africa, South America, and some areas of the Caribbean. Adults can range in size from a few millimeters to almost 8 cm. With the exception of the blood flukes, adult flukes are dorsoventrally flattened and have an oral sucker at the anterior end and a ventral sucker located midline, posterior to the anterior sucker. Except for the blood flukes, flukes are hermaphroditic, possessing male and female reproductive organs.

Fig. 28.49 shows the generalized life cycle of the liver, lung, and intestinal flukes. In all species, eggs must reach water to mature, and all have a snail species as the first intermediate host. The **miracidium** (first-stage larva) is ingested by a snail while within the egg or is released from eggs and penetrates the snail. Within the snail, a complex development of germinal tissue occurs, resulting first in sporocysts, which contain undifferentiated germinal structures, and then in rediae, which contain partially differentiated germinal material. The **cercaria** (second-stage larva) develops within the redia and is released into the water. Then, depending on the species, the cercaria attaches to aquatic vegetation or invades the flesh of aquatic organisms. At this stage, the organism is referred to as a **metacercaria** and is infective for humans. Except for the schistosomes, which infect humans by direct cercarial penetration, infection occurs when an individual ingests the metacercaria in raw or undercooked aquatic animals or on water vegetation. Prevention includes adequate cooking of water vegetation, fish, and crustaceans. In the case of the blood flukes, individuals should wear clothing and shoes to prevent cercarial penetration. Praziquantel is the recommended treatment for intestinal flukes, the liver fluke *Clonorchis sinensis*, the lung fluke *Paragonimus westermani*, and blood flukes. The liver fluke *Fasciola hepatica* is treated with triclabendazole.

The egg is the primary diagnostic stage. It is best detected on a wet mount of a concentrated specimen. Routine concentration procedures for feces, such as FES, may be used. The zinc sulfate method is not satisfactory, however, because all eggs except those of schistosomes are operculated. With the zinc sulfate method, the operculum might open and release the contents or cause the egg to sink. Table 28.7 compares the characteristics of fluke eggs.

Intestinal flukes

Fasciolopsis buski, known as the *giant intestinal fluke*, is found in the Far East, including China, Vietnam, and India. Dogs and pigs serve as reservoir hosts. Humans acquire the infection by ingesting metacercariae on freshwater vegetation, such as bamboo shoots and water chestnuts. Adults of *F. buski* live in the duodenum, where they cause mechanical and toxic damage. Inflammation and ulceration of the mucosa

Fig. 28.49 Life cycle of liver, lung, and intestinal flukes.

may be present. Heavy infections result in persistent diarrhea, anorexia, edema, ascites, nausea and vomiting, and/or intestinal obstruction.

Finding the adult or egg is diagnostic, although the egg is more commonly seen. The adult is flattened, is 2 to 7 cm long, and lacks the cephalic cone seen in *Fasciola hepatica*. Adults are usually not seen in a stool sample unless it is a purged specimen. Eggs are yellow to brown, average 130 to 140 μm by 80 to 85 μm in size, and have a small, relatively inconspicuous operculum. They are unembryonated when passed (Fig. 28.50). These eggs are identical to those of *F. hepatica* and, when seen, should be reported as *Fasciolopsis buski*/*Fasciola hepatica* eggs.

Metagonimus yokogawai and *Heterophyes heterophyes* are two small flukes found in the Far East and Middle East. Humans acquire infection with these organisms by ingesting the metacercariae in undercooked or raw fish. Adults live in the small intestine and produce few symptoms. A patient with a heavy worm burden may have diarrhea, colic, and loose stools, with a large amount of mucus. Adults of both species are small (1 to 2 mm) and delicate. Eggs serve as the primary diagnostic stage. They are 28 to 30 μm long and have a vase or flask shape. They are embryonated and operculated, with inconspicuous shoulders at the operculum. Eggs of these species resemble each other and those of *Clonorchis sinensis*.

Liver flukes

Fasciola hepatica, the sheep liver fluke, is seen in the major sheep-raising areas of the world, including parts of the southwestern United States. In addition, the organism is found in some cattle-raising areas. In sheep, the organism causes a disease known as *liver rot*, which is characterized by liver destruction. Humans acquire the infection by ingesting metacercariae on raw water vegetation, especially watercress. The larvae reach the liver by migrating through the intestinal wall and peritoneal cavity. Adults live in the biliary passages and gallbladder and rarely cause overt symptoms because infections are light. Tissue damage during migration through the liver can result in eosinophilia, an inflammatory reaction, secondary bacterial infection, and fibrosis in the biliary ducts. Heavy infections induce diarrhea, upper right quadrant abdominal pain, hepatomegaly, cirrhosis, and liver obstruction, with resulting jaundice. Chronic infections are usually asymptomatic.

Adults are approximately 3 cm long and have a prominent cephalic cone. The unembryonated, operculated eggs are carried in the bile to the intestinal tract and are passed in the feces. The size is 130 to 150 μm $\times$ 60 to 90 μm . They are almost indistinguishable from eggs of *F. buski* and are reported as *F. buski*/*F. hepatica* eggs (see Fig. 28.50).

Table 28.7 Comparisons of fluke eggs

Organism	Average size (μm) and shape	Other identifying features
<i>Fasciola hepatica</i> 	130 $\times$ 60–90, ellipsoidal	Small, indistinct operculum Yellow-to-brown color Unembryonated when passed
<i>Fasciolopsis buski</i> 	130 $\times$ 80–85, ellipsoidal	Cannot be distinguished from <i>F. hepatica</i> Unembryonated when passed
<i>Paragonimus westermani</i> 	80–115 $\times$ 48–60, oval	Brown, thick shell Slightly flattened operculum Shoulders at operculum Unembryonated when passed
<i>Clonorchis sinensis</i> 	29–35 $\times$ 12–19, vase shaped	Domed operculum Prominent shoulders Knob at end opposite operculum Embryonated when passed
<i>Heterophyes heterophyes</i> and <i>Metagonimus yokogawai</i> ^a	28–30 $\times$ 15–17, vase shaped	Operculated Shoulders not distinct Small knob Embryonated Similar to <i>C. sinensis</i>
<i>Schistosoma mansoni</i> 	115–175 $\times$ 45–75, oval	Lateral spine No operculum Embryonated when passed
<i>Schistosoma haematobium</i> 	110–170 $\times$ 40–70, oval	Rounded anterior Terminal spine Embryonated when passed
<i>Schistosoma japonicum</i> 	60–95 $\times$ 40–60, round to slightly oval	Small, inconspicuous, hooked lateral spine Embryonated when passed

^aThe eggs of these two species, *C. sinensis*, and *Opisthorchis*, are almost indistinguishable.

The Chinese or Oriental liver fluke, *Clonorchis sinensis*, is geographically limited to the Far East, where dogs and cats serve as reservoir hosts. *Opisthorchis* spp. are additional liver flukes found in humans. *Opisthorchis viverrini* is known as the Southeast Asian liver fluke, and *Opisthorchis felinus* is known as the cat liver fluke. The adults live in the distal portion of the bile ducts. As with *F. hepatica*, light infections produce few or no symptoms. Repeated or heavy infections cause inflammation because of mechanical irritation, fever, diarrhea, pain, fibrotic changes, or obstruction of the bile duct. Humans acquire the infection by ingesting the metacercariae in raw, undercooked, or pickled fresh-water fish.

The diagnosis is made by finding ova in feces or, occasionally, in duodenal aspirates. Adults are thin, tapered at both ends, and 1 to 2.5 cm long. It is difficult to

Fig. 28.50 *Fasciolopsis buski*/*Fasciola hepatica* egg (unstained, $\times 400$).

Fig. 28.51 *Clonorchis sinensis* egg (unstained, $\times 1000$).

distinguish the ova of *Clonorchis*, *Opisthorchis*, *Heterophyes*, and *Metagonimus*. The egg is 29 to 35 μm long, embryonated when passed, flask shaped, and operculated, with prominent shoulders at the operculum and a knob at the opposite end (Fig. 28.51).

Lung flukes

Organisms of the genus *Paragonimus* usually infect tigers, leopards, dogs, and foxes. About 30 species of *Paragonimus* have been named, and 9 have been identified as human parasites. An estimated 20 million people suffer from paragonimiasis. *Paragonimus westermani*, the lung fluke, is found primarily in Southeast Asia and in focal areas of Latin America and Africa. It is the most common species affecting humans. *Paragonimus kellicoti* is occasionally found in North America.

Humans acquire the infection by ingesting metacercariae in raw, pickled, wine-soaked, or undercooked freshwater crabs or crayfish. The metacercaria excysts in the small intestine and burrows through the duodenal wall into the peritoneal cavity. It eventually penetrates the diaphragm and enters the lung. The host shows few symptoms during this migration but may exhibit intermittent coughing and chest pain. The parasite induces an inflammatory response in the lung characterized by the presence of neutrophils and eosinophils. Major symptoms associated with lung habitation are nonspecific and often include persistent cough, chest pain, and hemoptysis. Adults, which are reddish brown and approximately 1 cm long, live within capsules in the bronchioles.

Sputum is the primary diagnostic specimen. Eggs are expelled from the capsule into the bronchioles and carried upward in the sputum. Eggs may be found in feces if they have been coughed up and subsequently swallowed. *P. westermani* eggs are yellowish-brown, are broadly oval, are 80 to 115 $\mu\text{m} \times 48$ to 60 μm in size, and have a flattened operculum and slight shoulders. They are unembryonated when passed. The shell thickens at the end opposite the operculum (Fig. 28.52). These eggs can appear similar to those of *Diphylllobothrium latum* and must be carefully examined when seen in the feces. A wet mount of sputum demonstrates the egg in some patients.

Fig. 28.52 *Paragonimus westermani* egg (unstained, $\times 400$).

Blood flukes

Blood flukes, *Schistosoma* spp., differ from other flukes in the following manner:

- Both male and female forms exist; the female lives in an involution chamber, the gynecophoral canal, which extends the length of the male.
- The eggs are unoperculated.
- Humans are infected by direct cercarial penetration of skin.
- The flukes have a cylindric shape, rather than being dorsoventrally flattened.

The three primary species of schistosomes pathogenic to humans are *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum*. Male adult schistosomes measure 7 to 20 mm, and adult females measure 7 to 26 mm. *S. mansoni*, which is commonly found in Africa, parts of South America, the West Indies, and Puerto Rico, lives in venules of the mesentery and large intestines. *S. japonicum*, which is commonly found in the Far East, including Japan, China, and the Philippines, lives in venules of the small intestine. This species, unlike the other two, has many mammalian reservoir hosts. *S. haematobium*, which is primarily found in the Nile Valley, the Middle East, and East Africa, lives in the veins surrounding the bladder. Two additional species pathogenic for humans are *S. intercalatum* and *S. mekongi*.

Clinical infections

Schistosomiasis (bilharziasis) affects approximately 200 million people worldwide. Symptoms are related to the phases of the fluke's life cycle and location of the adults. Cercarial penetration may cause a self-limiting local dermatitis, including irritation, redness, and rash, that persists for approximately 3 days. Larval migration through the body causes generalized symptoms, such as urticaria, fever, and malaise, which can last up to 4 weeks. The presence of the migrating larvae and adults in the veins causes little inflammatory damage seemingly because they acquire host HLAs and ABO blood group antigens on their surface that diminish the host's immune response.

Egg production and egg migration through the tissues are responsible for most of the immediate damage because the eggs are highly immunogenic. After release by the adult female, the eggs secrete enzymes and begin to penetrate

vessel walls and tissue. Eggs subsequently find their way into the lumen of the intestines or bladder. The egg spines cause trauma to the tissues and walls of the vessels during the early stage of acute infections and can result in gross or microscopic hematuria (*S. haematobium*) or diarrhea (*S. mansoni* and *S. japonicum*). In some individuals, especially those heavily infected with *S. japonicum*, an acute serum sickness-like illness (Katayama fever) occurs during the initial egg-laying period. This is induced by hypersensitivity response to egg antigens and is characterized by increased circulating levels of immune complexes and eosinophils.

In chronic infections, the eggs remaining in the tissue induce an immune response, resulting in granuloma formation, which leads to thickening and fibrotic changes. Scarring of the veins, development of ascites, pain, anemia, hypertension, hepatomegaly, and splenomegaly are also seen. In urinary schistosomiasis, microscopic bleeding into urine is present during the acute phase. In chronic stages, dysuria, urine retention, and urinary tract infections occur.

Penetration of humans by cercariae of the flukes of birds and other mammals causes schistosomal dermatitis, commonly referred to as *swimmer's itch*. Foreign proteins from these cercariae elicit a tissue reaction characterized by small papules 3 to 5 mm in diameter, edema, erythema, and intense itching. Symptoms last about 1 week and disappear as cercariae die and degenerate.

Life cycle

The life cycles of all three schistosomes are identical (Fig. 28.53). The eggs are embryonated when excreted, and the miracidium is released when the egg reaches water. After

the miracidium penetrates a snail (the first intermediate host), sporocysts and then cercariae are produced during a 6-week period. Cercariae migrate from the snail into water. Cercariae, with the help of enzymes, penetrate intact human skin. Once in the vasculature, they shed their forked tails and are referred to as *schistosomula*. They circulate until they reach the lungs or enter the liver, where maturation and pairing of the female and male are completed. The adults use oral and ventral suckers for attachment. The paired adult flukes use the portal system to reach veins of the intestine or bladder. Adults living in the veins can be killed with praziquantel, but the drug has no effect on the eggs in tissues.

Laboratory diagnosis

Diagnosis is made by finding embryonated eggs in feces (*S. mansoni* and *S. japonicum*) or in urine (*S. haematobium*). The egg of *S. mansoni* (Fig. 28.54A) is yellowish, elongated, 115 to 175 $\mu\text{m} \times 45$ to 75 μm in size, and has a prominent lateral spine. *S. haematobium* eggs (see Fig. 28.54B) are elongated, 110 to 170 $\mu\text{m} \times 40$ to 70 μm in size, and have a terminal spine. *S. japonicum* eggs (see Fig. 28.54C), which resemble *S. mekongi* eggs, are round, 60 to 95 $\mu\text{m} \times 40$ to 60 μm in size, and have a small, curved, rudimentary spine that might be obscured. The best time to collect eggs in urinary schistosomiasis is during peak excretion time in the early afternoon (noon to 2 PM). Biopsy may also be used in the diagnosis of schistosomiasis. Serodiagnosis can be useful to diagnose infection in patients from nonendemic countries who develop symptoms after visiting endemic areas. In areas of endemicity, serum antibody testing cannot differentiate between active and non-active infections. A urine-based, point-of-care, rapid test strip

Fig. 28.53 Life cycle of blood flukes (*Schistosoma* spp.).

for the detection of parasite antigen (circulating cathodic antigen) is commercially available and useful for field screening in endemic areas.

Tapeworms

Tapeworms (cestodes) are another group of human parasites in the phylum Platyhelminthes. They show extensive size variation, ranging from 3 mm to 10 m, generally require intermediate hosts in their life cycle, and are hermaphroditic. They are ribbonlike organisms, whose method of growth involves the addition of segments, termed *proglottids*. Each proglottid, when mature, produces eggs infective for the intermediate host. Fig. 28.55 shows a general diagram of the tapeworm. The anterior headlike segment of a tapeworm, or **scolex**, has suckers and, in some species, hooklets as a means of attachment to the intestinal mucosa. The neck, located directly behind the scolex, is where proglottid production occurs. Treatment is targeted at detaching the scolex from the mucosa. Gravid proglottids at the distal end of the organism discharge eggs into feces.

Eggs of most of the tapeworms contain a **hexacanth embryo** or **oncosphere** (tapeworm embryo with three pairs of hooks that is infective for the intermediate host). Transmission to humans involves ingestion of a larval stage, called the **cysticercus** (larva consisting of a fluid-filled sac containing an invaginated scolex), cysticeroid, or plerocercoid larva (depending on the genus) in raw or undercooked meat or fish or of insects harboring the larval stage. The larval stage contains an invaginated scolex inside a protective membrane.

Table 28.8 Comparisons of tapeworm eggs

Organism	Average size (μm) and shape	Other identifying features
<i>Diphyllobothrium latum</i> 	58–76 $\times$ 40–50, oval	Inconspicuous operculum Small knob at end opposite operculum Unembryonated when passed
<i>Taenia</i> spp. 	30–35, round	Thick, brown, radially striated shell Embryonated, with six-hooked oncosphere when passed
<i>Hymenolepis nana</i> 	30–47, oval	Two membranes—inner has two polar knobs, from which four polar filaments extend into space between inner and outer membranes Embryonated, with six-hooked oncosphere when passed
<i>Hymenolepis diminuta</i> 	50–75, round to slightly oval	Two membranes—inner has very slight polar knobs No polar filaments Embryonated, with six-hooked oncosphere when passed
<i>Dipylidium caninum</i> 	20–40 (each egg), round; resembles <i>Taenia</i> spp.	Eggs passed in packet of 15–25 Eggs embryonated, with six-hooked oncosphere when passed

The diagnosis of tapeworm infection is usually made by finding eggs in feces, although proglottids can be used if they are passed intact. Intestinal tapeworm infections are usually treated with praziquantel; alternatively, they can be treated with niclosamide, albendazole, or nitazoxanide. Table 28.8 compares the characteristics of tapeworm eggs.

Diphyllobothrium latum

D. latum, the fish tapeworm, is found worldwide in areas in which the population eats pickled or raw freshwater fish. In the United States, it is primarily seen in the areas around the Great Lakes. Fish-eating mammals in endemic areas may also be infected. Humans usually harbor only a single worm, which attaches in the jejunum and can reach a length of up to 10 m. Most infected individuals demonstrate no clinical symptoms; others have vague GI symptoms, including nausea and vomiting and intestinal irritation. The organism may cause a vitamin B₁₂ deficiency, especially in persons of northern European descent, and long-term infection may lead to megaloblastic anemia.

The life cycle of *D. latum* is somewhat of a hybrid between that of the flukes and that of the tapeworms (Fig. 28.56). The operculated, unembryonated egg, passed in human feces, must reach water to mature. The first larval stage (coracidium) is ingested by a copepod and develops into a procercoid larva within the copepod. When the infected copepod is ingested by a fish, the larva leaves the fish's intestine and invades the flesh, where it develops into a plerocercoid larva, which consists of a scolex with a thin, ribbonlike portion of tissue. Humans ingest the plerocercoid larvae by eating raw or undercooked fish. The scolex is released in the intestine, where it develops into an adult worm.

The scolex, proglottid, and egg are diagnostic structures that can be found in fecal specimens. The egg, however, is usually detected. The egg is unembryonated when passed, operculated, and yellow to brown (Fig. 28.57). It is about 58 to 76 $\mu\text{m} \times$ 40 to 50 μm in size and has a small, knoblike protuberance at the end opposite the operculum. The knob may not be seen on all eggs, so size and lack of shoulders must be used to distinguish the egg from that of *Paragonimus westermani*. The proglottid is wider than it is long, with a characteristic rosette-shaped or coiled uterus. The scolex, which is 2 to 3 mm long, is elongated and has two sucking grooves, one located on the dorsal surface and the other on the ventral surface, and no hooks.

Taenia

Two *Taenia* spp. infect humans: (1) *Taenia saginata*, the beef tapeworm, which is found primarily in beef-eating countries of the world, and (2) *Taenia solium*, the pork tapeworm, which is found in areas of the world with a high consumption of pork, such as Latin America. Both organisms attach to the intestinal mucosa of the small intestine. The adult *T. saginata* can reach a length of 10 m, whereas the adult *T. solium* may reach only 7 m. Infection with the adult tapeworm of either species usually causes few clinical symptoms, although vague abdominal pain, indigestion, and loss of appetite may be present. The major complication of infection with *T. solium* is cysticercosis, in which the infected individual becomes the intermediate host and harbors the larvae in tissues. This is discussed in the section on tissue infections with cestodes (see the "Cysticercosis" section later in this chapter).

As noted, the life cycles of the two *Taenia* spp. (Fig. 28.58) are identical except that humans may also serve as intermediate

Fig. 28.56 Life cycle of *Diphyllbothrium latum*.

Fig. 28.57 *Diphyllbothrium latum* egg (unstained, $\times 400$).

hosts for *T. solium*. Embryonated eggs are passed in human feces and ingested by the intermediate host. The oncosphere is freed in the intestinal tract, migrates through the intestinal wall, and gains access via the circulatory system to the muscles of the host, where it transforms into a cysticercus. When humans ingest raw or undercooked meat, the scolex in the cysticercus is freed, attaches in the human small intestine, and matures into the adult tapeworm within 10 weeks. The proglottids are motile and, if broken off in the intestinal tract, may actively migrate out via the anus.

Laboratory diagnosis of *Taenia* infection can be made by finding the egg, scolex, or proglottid in the feces. The egg, which is the most common stage found, is yellow to brown, round, and surrounded by a thick wall with radial striations; it measures 30 to 35 μm in diameter. The egg is embryonated, with a six-hooked oncosphere when passed in feces (Fig. 28.59). Eggs of these species are indistinguishable and must be reported as *Taenia* sp. eggs. Gravid proglottids may be seen in the stool specimen and can be used to differentiate the two species. Proglottids of *T. solium* have 7 to 13 primary uterine branches on each side of the main uterine trunk, whereas proglottids of *T. saginata* show 15 to 20 per side. The scolex, if found, can also be used to distinguish the organisms. The scolex of *T. saginata* is less than 5 mm long and has four suckers, whereas that of *T. solium* has a rostellum, with a double row of 25 to 30 hooklets in addition to the four suckers.

Hymenolepis

The dwarf tapeworm, *Hymenolepis nana*, is found worldwide and is a common tapeworm in children, whereas *Hymenolepis diminuta*, the rat tapeworm, is seen less frequently. Light infections are usually asymptomatic; large numbers of worms may cause abdominal pain, diarrhea, irritability, and headache. Infections with *H. nana* are easily transmitted among children because an intermediate host is not required. Direct fecal-oral transmission of the egg, development of the cysticercoid in

Fig. 28.58 Life cycle of *Taenia* spp.

Fig. 28.59 *Taenia* sp. embryonated egg (unstained wet mount, $\times 400$).

the intestinal tissue of the host, and reentry into the lumen for development into an adult characterize the life cycle (Fig. 28.60). This autoinfective life cycle is most common, although an insect vector may serve as an intermediate host in an alternative form of the life cycle.

The adult *H. nana* is approximately 40 mm long and has a small scolex, with four suckers and a rostellum with spines.

The primary method of diagnosis is finding the egg in a stool specimen. The egg is spherical to oval, measures 30 to 47 μm , and has a grayish color. The hexacanth embryo is contained within an inner membrane, and the area between the inner membrane and egg wall contains two polar thickenings from which four to eight polar filaments extend (Fig. 28.61). Infection with *H. diminuta* is acquired by ingesting fleas that contain the infective cysticercoid. The adult tapeworm is 20 to 60 cm long. The egg, which must be distinguished from that of *H. nana*, is 50 to 75 μm , gray or straw colored, and oval. An inner membrane with inconspicuous polar thickenings but no polar filaments surround the oncosphere (Fig. 28.62).

Dipylidium caninum

Humans serve as accidental hosts for *Dipylidium caninum*, the dog tapeworm. Children are usually infected by ingesting fleas containing the larval stage. The resulting infections generally do not cause any symptoms. The proglottid may be seen in human feces and is characterized by its pumpkin-seed shape, twin genitalia, and the presence of two genital pores, one on each side of the proglottid. The eggs are characteristically seen in packets of 15 to 25 eggs. Individual eggs are 20 to 40 μm in size and resemble those of *Taenia* spp. (Fig. 28.63).

Tissue infections with cestodes

Cysticercosis, sparganosis, and hydatid cyst disease are the major diseases caused by the tissue stage of a tapeworm. They originate when a human accidentally becomes the intermediate host for the parasite.

Cysticercosis

Cysticercosis results when a human ingests the infective eggs of *T. solium*, the pork tapeworm, thus becoming an intermediate host. The disease is endemic in areas of rural Latin America, Asia, and Africa and is reemerging as a zoonosis in the United States as a result of immigration of persons from

Fig. 28.63 *Dipylidium caninum* egg packet (unstained, $\times 400$).

endemic areas. Contributing factors for infection include poor hygiene and sanitary habits that result in ingestion of food containing an infective egg as well as residence in rural areas and hog farming. Once the egg is ingested, the hexacanth embryo is released into the intestines, penetrates the intestinal wall, and enters the circulation to develop as a cysticercus in any tissue or organ. The larva can live up to 7 years and elicits a host tissue reaction, resulting in production of a fibrous capsule. Once the organism dies and releases larval antigens, there is an intense host inflammatory reaction that leads to tissue damage in the area. Eventual calcification of the cysticercus will occur. The most commonly infected sites are the striated muscle, eye, and brain.

Light infections usually cause no clinical symptoms. When present, symptoms depend on the organ affected and the size and number of cysticerci present. Muscular pain, weakness, and cramps characterize infections of the striated muscle. A cysticercus can form in the vitreous or subretinal space of the eye. Retinal detachment, intraorbital pain, flashes of light, and blurred vision may occur. Neurocysticercosis, which is the most serious manifestation, is the causative agent for up to 30% of epilepsy cases seen in patients in countries where the disease is endemic. In the United States, the condition is often seen in Hispanic immigrants from endemic areas. Infection may be manifested by headaches, symptoms resembling those seen in meningitis or a brain tumor, convulsions, or a variety of motor and sensory problems.

The cysticercus is oval, translucent, and about 5 to 18 mm in size. It contains an invaginated scolex containing four suckers and a circle of hooklets on the rostellum. The infection may be diagnosed by various methods, including radiography to detect calcified cysts, ophthalmoscopic examination of the eye to detect cysticerci, imaging techniques (CT and MRI) to locate larvae in the brain, and biopsy and histologic staining of tissue. Serologic tests, including immunoblot techniques, have been developed to detect antibodies against specific cysticercal antigens. These are most useful in epidemiologic studies.

Sparganosis

Human infection with the plerocercoid larva (sparganum) of a dog or cat tapeworm can result in sparganosis. Humans acquire the infection by ingesting a copepod containing the proceroid larva; by ingesting reptiles, amphibians, or other

animals containing the plerocercoid larva; or through invasion by the plerocercoid larva when the raw tissue from the second intermediate host is used as a poultice. The disease is most common in Southeast Asia. Infection is often seen in the eye after a poultice has been applied to relieve an infection. The organism may also cause migratory subcutaneous nodules, itching, and pain. The diagnosis of sparganosis is made by finding a small, white, ribbonlike organism with a rudimentary scolex. Size ranges from a few millimeters to 40 cm. The organism may be removed surgically.

Echinococcosis

Echinococcosis (hydatid cyst disease) is an infection by *Echinococcus granulosus* that normally involves the dog or another member of the family Canidae as the definitive host. Sheep and other herbivores are the usual host of the larval stage (hydatid cyst). The disease is primarily seen in sheep-raising areas of the world, including Australia, southern South America, and parts of the southwestern United States.

The adult worm is approximately 5 mm long and contains only three proglottids. The eggs are found in the feces of dogs or other definitive hosts and resemble those of *Taenia* spp. A human becomes an intermediate host by accidentally ingesting the eggs of *E. granulosus* containing the hexacanth embryo. The oncosphere is liberated in the intestine, penetrates the mucosa, enters the circulation, and usually lodges in the liver. The embryo develops a central cavity-like structure lined with a germinal membrane, from which brood capsules and protoscolices (hydatid sand) develop. The hydatid cyst's size is limited by the organ in which it develops. In bone, a limiting membrane never develops, so the cyst fills the marrow and eventually erodes the bone.

Symptoms differ, depending on the organ infected. Pressure from the increasing size of a cyst may cause necrosis of surrounding tissue. Rupture of the cyst liberates large amounts of foreign protein (allergen) that may elicit an anaphylactic response. In addition, freed germinal epithelium may serve as a source of new infection. The diagnosis can be made by radiologic examination, ultrasonography, or other imaging techniques. Aspiration of the cyst contents usually reveals the presence of protoscolices.

Roundworms

Human roundworms include those that infect the intestinal tract and blood and tissue. These organisms, found worldwide, are transmitted by the ingestion of the embryonated egg or by direct penetration of skin by larvae in the soil, or they may require an insect vector. Intestinal roundworms are the most common of all the helminths that cause human infections in the United States. Infected individuals are found in highest numbers in warm, moist areas of the Southeast and in areas with poor sanitation.

Roundworms are characterized by the presence of two sexes and a life cycle that may involve larval migration throughout the body. The adults obtain nourishment by absorbing nutrients from partly digested intestinal contents or by sucking blood. Patients may be asymptomatic or symptomatic; the severity of the symptoms is related to the worm burden, host's nutritional status and age, and duration of

Table 28.9 Comparisons of intestinal roundworm eggs and larvae

Organism	Average size (μm) and shape	Other identifying features
<i>Ascaris lumbricoides</i> Fertile 	45–75 $\times$ 35–50, oval	Bile-stained shell Bumpy, mammillated In one-cell stage when passed Some eggs may be decorticated (lack mammillated coat)
Infertile 	85–95 $\times$ 43–47, oval (some bizarrely shaped)	Mammillated Thin shell Undifferentiated internal granules
<i>Enterobius vermicularis</i> 	50–60 $\times$ 20–30, oval, flattened on one side	Colorless shell Usually embryonated with C-shaped larva
<i>Trichuris trichiura</i> 	50–55 $\times$ 22–23, barrel shaped	Bile-stained, thick shell Hyaline polar plugs Unembryonated when passed
Hookworm egg 	50–60 $\times$ 35–40, broadly oval	Thin shell, colorless In four- to eight-cell stage when passed
Rhabditiform larva 	250–300	Long buccal capsule Inconspicuous genital primordium
Filariform larva 	500	Pointed tail Esophageal-to-intestinal ratio 1:4
<i>Strongyloides stercoralis</i> Rhabditiform larva 	Egg rarely seen; resembles that of hookworm 200–250	Short buccal capsule Prominent genital primordium
Filariform larva 	500	Notched tail Esophageal-to-intestinal ratio 1:1

infection. Most roundworm infections can be treated with oral administration of albendazole or mebendazole. Table 28.9 compares the diagnostic characteristics of the eggs and larvae of intestinal roundworms.

Enterobius vermicularis

E. vermicularis, often called the *pinworm*, is a worldwide parasite commonly detected in children, especially those 5 to 10 years of age. It is estimated that 20 million to 40 million individuals are infected in the United States alone. Key risk factors for this infection are inadequate personal and community hygiene. Enterobiasis is frequently found in families, kindergartens, daycare centers, or crowded conditions in which the eggs can be easily transmitted. The eggs are resistant to drying and are easily spread in the environment. Adult worms live in the large intestine (cecum), although they have occasionally

been found in the appendix or vagina. Ectopic infections have also caused endometritis, urethritis, and salpingitis. There is evidence that the organism may also be associated with urinary tract infections in young girls.

Although patients with *E. vermicularis* infection are often asymptomatic, they may experience loss of appetite, abdominal pain, loss of sleep, and nausea and vomiting. Anal pruritus is caused by migration of the female worm to the perianal area. The life cycle of this organism (Fig. 28.64) is characterized by migration of the female out through the anus at night to lay eggs in the perianal area. The eggs are infective with a third-stage larva within several hours of being laid. Typically, transmission involves inhalation or ingestion of the infective eggs. Direct anal-oral transmission occurs in children as a result of poor hand washing or fingernail biting. Autoinfection, in which the hatched larvae reenter the intestine to mature into an adult, may also occur.

Fig. 28.64 Life cycle of *Enterobius vermicularis*.

Treatment for pinworm includes mebendazole, pyrantel pamoate, or albendazole. Treatment requires an initial dose followed by an additional treatment 2 weeks later to prevent reinfection caused by ingestion of eggs remaining in the environment.

Because eggs are laid outside the body in the perianal area and are rarely present in the stool, a fecal specimen is unsatisfactory for diagnosis. The cellophane tape preparation or commercially available sticky paddle is considered the diagnostic method of choice. The procedure must be done as soon as the child arises in the morning. The perianal area is touched with the sticky side of the tape or paddle. The adult female can occasionally be seen in this preparation. Because the gravid female can migrate into the vagina, eggs can also be seen in vaginal specimens.

The adult female measures 8 to 13 mm long and has a long, pointed tail and three cuticle lips, with alae at the anterior end. The less commonly seen male is 2 to 5 mm long, with a curved posterior. The egg is oval, colorless, and slightly flattened on one side. It measures approximately 50 to 60 μm $\times$ 20 to 30 μm . The egg is usually seen embryonated, with a C-shaped larva (Fig. 28.65).

Fig. 28.65 *Enterobius vermicularis* egg (unstained, $\times 400$).

Trichuris trichiura

Ascaris lumbricoides, *T. trichiura*, and two genera of hookworms, *Ancylostoma* and *Necator*, are the most common soil-transmitted helminths. These organisms have a worldwide distribution and are major causes of morbidity, rather than death, in developing areas of the world. Estimates indicate that 25% of the world's population is infected with

one or more of these organisms. Chronic infection caused by these helminths, especially hookworm, can adversely affect physical and mental development in children. A heavy worm burden is more likely to result in complications. Some of the risk factors for infection include poor sanitation (personal and community), poverty, occupation, and climate (necessary for maturation and survival of the eggs in the soil). *Strongyloides stercoralis* is also a soil-transmitted helminth but does not have the broad geographic distribution of the other organisms.

T. trichiura, referred to as the *whipworm*, is found worldwide, especially in areas with a moist, warm climate. It is found in the southeastern United States, often as a co-infection

Fig. 28.66 *Trichuris trichiura* egg (unstained, $\times 400$).

with *A. lumbricoides*. Light infections with *T. trichiura* rarely cause symptoms; heavy infections result in intestinal bleeding, weight loss, abdominal pain, nausea and vomiting, and chronic diarrhea. As the adults thread themselves through the intestinal mucosa, inflammation develops. Prolonged heavy infection can result in colitis or diarrhea with blood-tinged stools. Rectal prolapse can be the result of repeated heavy infections in undernourished children. Hypochromic anemia may occur in children with inadequate iron and protein intake in the presence of constant, low-level bleeding with chronic infection. Treatment includes mebendazole or albendazole.

Eggs are passed in feces and require at least 14 days in warm, moist soil for embryonation to occur. Humans acquire infection by ingesting the infective egg. The larva is released in the small intestine and undergoes several molts before maturing into an adult worm in the cecum. The egg and occasionally the adult of *T. trichiura* may be seen in fecal specimens. The adult male measures 30 to 45 mm and has a thin anterior and a thick, coiled posterior. The female is 30 to 50 mm long, with a thin anterior and thick, straight posterior. Eggs are the typical diagnostic form. They are brown, barrel-shaped, unembryonated when passed, and 50 to 55 $\mu\text{m} \times 22$ to 23 μm in size, with a thick wall and hyaline polar plugs at each end (Fig. 28.66).

Ascaris lumbricoides

An estimated 1 billion people worldwide are infected with *A. lumbricoides*. The organism is most common in tropical and subtropical areas, and in areas of poor sanitation. Children are most commonly infected. Infections are uncommon in the United States, but the organism is most frequently seen in rural parts of the Southeast. Transmission is primarily by the fecal-oral route, and clinical symptoms may be related to the different phases of the life cycle. The organism is often found concurrently with whipworm.

Abdominal discomfort, loss of appetite, and colicky pains are caused by the presence of adult worms in the intestine. There is evidence that heavy infections may contribute to lactose intolerance and malabsorption of some vitamins, including vitamin A. In children, large numbers of adult worms can cause intestinal obstruction. Because the worms feed on liquid intestinal contents, chronic infection with *A. lumbricoides*

in children may hamper growth and development. Larvae migrating through the lungs can cause an immune response in the host characterized by asthma, edema, pneumonitis, and eosinophilic infiltration. Rarely, larvae are seen in the sputum in heavy infections. Occasionally, fever or other disease conditions cause the adults to migrate from the intestine and invade other organs, resulting in peritonitis, liver abscess, or secondary infection in the lungs. Adults may also exit through the mouth, tear duct, or nose and have been reported to enter and block catheters. Eosinophilia may be present. Albendazole or mebendazole are the drugs of choice for treating infection with *Ascaris*.

Eggs that are deposited in warm, moist soil become infective within about 2 weeks. After the egg is ingested, larvae hatch in the duodenum, penetrate the intestinal wall, and gain access to the hepatic portal circulation. They break out from the capillaries into the lungs, travel up the bronchial tree and trachea and over the epiglottis, and are swallowed. Maturation is completed in the intestine. The life cycle (Fig. 28.67) takes about 50 days after infection until adults are mature. The usual diagnostic stage is the egg. Fertile *Ascaris* eggs are oval, measure 45 to 75 $\mu\text{m} \times 35$ to 50 μm , and have a thick hyaline wall surrounding a one-cell-stage embryo. Most eggs have a brown, bile-stained, mammillated outer layer (Fig. 28.68). Some eggs, described as *decorticated*, lack the mammillated outer coat. Infertile eggs, up to 90 μm in length, are often elongated and contain a mass of highly refractile granules. Adults, measuring 15 to 35 cm long and about the diameter of a lead pencil, may be seen in stool samples. The female has a straight posterior, and the male has a curved posterior. Both have three anterior lips with small, toothlike projections.

Hookworms

Worldwide, about 740 million people are estimated to be infected with hookworms. The greatest incidence is in the tropics and subtropics, particularly Asia, Latin America, the Caribbean, and sub-Saharan Africa. In the United States in the 1950s, hookworm infection was very common, particularly in the South. Improved sanitation has greatly reduced the incidence. Unlike other helminths, in which infection peaks in childhood and adolescence, the hookworm burden often increases with age. Classically, two species of hookworm, *Necator americanus* (New World) and *Ancylostoma duodenale* (Old World), were known to infect humans. Recently an animal parasite, *Ancylostoma ceyanicum* (prevalent in Southeast Asia, Australia, and the Pacific Islands) was recognized as a human pathogen. *A. duodenale* is seen in southern Europe and northern Africa along the Mediterranean as well as in parts of Southeast Asia and South America. *N. americanus* has a geographic distribution in Africa, Southeast Asia, and South and Central America and is endemic in rural areas of the southeastern United States.

Adults of the three species can be differentiated by the morphology of the buccal capsule or, in the male, the copulatory bursa. The eggs, however, are identical. These worms live in the small intestine and attach to the mucosa by means of teeth (*A. duodenale*) or cutting plates (*N. americanus*). They digest the tissue plug and pierce capillaries. Once attached, they continue to ingest blood as a source of nourishment by secreting anticoagulants, platelet inhibitors, and substances

Fig. 28.67 Life cycle of *Ascaris lumbricoides*.

Fig. 28.68 *Ascaris lumbricoides* egg, fertile (unstained, $\times 400$).

that interfere with the tissue factor–factor VIIa complex. The organisms also secrete substances that interfere with the action of digestive enzymes and inhibit host absorption of nutrients.

Clinical symptoms differ according to the phase of the life cycle and the worm burden. A small, red, itchy papule,

referred to as *ground itch*, develops at the site of larval penetration. If large numbers of larvae are present during the lung phase of migration, the patient may have bronchitis, but unlike with *Ascaris* larvae, no host sensitization occurs. The most severe symptoms are associated with the adult, including nonspecific symptoms such as diarrhea, fever, and nausea and vomiting. Eosinophilia is often present. A few patients may experience pica and then ingest dirt (geophagia).

Blood loss, ranging from 0.03 to 0.2 mL per worm per day, is primarily the result of the ingestion of blood by the adult worm. Hemorrhages at the site of attachment, however, also contribute to total blood loss. Chronic heavy hookworm infection can lead to microcytic hypochromic anemia, especially in children whose diet is inadequate in iron and protein. A chronic heavy infection may affect the mental and physical development of a child because of the complications of anemia and malnutrition. Infection is usually treated with albendazole or mebendazole. Supportive therapy, including iron and protein supplements, may be needed in severe cases, especially if the child shows evidence of anemia or if the infection occurs in a pregnant woman. Vaccine development using hookworm antigens is being targeted as a way to help control infections.

Case check 28.2

The patient in the Case in Point shows several characteristics associated with hookworm infection. The vesicular lesions on the foot (ground itch) represent sites at which filariform larvae have penetrated skin and entered the blood circulation. In the case of other roundworms, the egg is usually ingested; in the case of tapeworms, there could possibly be a history of eating raw or undercooked meat.

The presence of a low hemoglobin level and microcytic hypochromic anemia is common in severe or long-term hookworm infection because the organism attaches to the intestinal mucosa and uses blood as a source of nourishment. The long-term, low-level blood loss will cause this type of anemia, characteristic of iron-deficiency anemia, in individuals who are malnourished or lack adequate dietary iron.

When the eggs are deposited in warm, moist soil, the non-infective, feeding, first-stage **rhabditiform larva** develops within 1 to 2 days and feeds on bacteria in the soil. A non-feeding, infective, filariform larva develops within 1 week. Humans are infected when the filariform larvae penetrate skin. The organisms enter the circulation and break out of the capillaries into the lung and then migrate up the bronchial tree, over the epiglottis, and into the digestive tract. After additional larval molts, the worms attach to the mucosa in the small intestine. Eggs are produced within 6 to 8 weeks

after skin penetration by the filariform larva. Fig. 28.69 shows the life cycle of the hookworm.

Adult hookworms are rarely seen in stool specimens; the egg and the rhabditiform larva are the usual diagnostic stages. The eggs and rhabditiform larvae of the three species are indistinguishable; therefore the laboratory report can only state "hookworm" when a characteristic egg or larva is found in a stool specimen. The egg is oval, colorless, thin shelled, and 50 to 60 μm long and usually contains an embryo in the four- to eight-cell stage of cleavage (Fig. 28.70). The rhabditiform larva must be differentiated from that of *S. stercoralis* because treatment is different. The hookworm rhabditiform larva is 250 to 300 μm long and has a small, inconspicuous, genital primordium (Fig. 28.71A) and a long buccal capsule (see Fig. 28.71B). The filariform larva also must be distinguished from that of *S. stercoralis*. Hookworm filariform larvae are about 500 μm long, with a pointed tail and an esophageal-intestinal ratio of 1:4.

Strongyloides stercoralis

S. stercoralis, known as the *threadworm*, inhabits the small intestine but is also capable of existing as a free-living worm. It is endemic in the tropics and subtropics, including Southeast Asia, Latin America, and sub-Saharan Africa but has been found on all continents except Antarctica. It is estimated that 30 million to 100 million people are infected worldwide. *S. stercoralis* can persist in the host for decades after initial infection, and infection may progress to hyperinfection if the

Fig. 28.69 Life cycle of the hookworm.

host becomes immunocompromised. In the United States, the prevalence rate ranges from 0.4% to 4%, with most cases found in people living in Appalachia, people living in rural areas of the Southeast, or immigrants from endemic areas.

Although many patients with *S. stercoralis* infection are asymptomatic, some may exhibit fever, nausea and vomiting, tracheal irritation, and sharp, stabbing pains that resemble those of an ulcer or other GI diseases, including pancreatitis. Chronic mild diarrhea may be present. The eosinophil count is often elevated—in some cases, up to 40%. Unlike hookworms, *S. stercoralis* larval penetration of skin does not cause a prominent papule, and migration through the lungs rarely elicits pneumonitis, but the patient may have wheezing and a mild cough.

In contrast with the mild symptoms in an immunocompetent host, patients with a drug-induced immunocompromised state (corticosteroids), lymphoma, human T-lymphotropic virus 1 infection, malignancy, or other conditions that cause T-cell depletion can develop severe infections, referred to as *disseminated strongyloidiasis* or *hyperinfection*. In this population, large numbers of the filariform larvae develop in the intestine in an autoinfective cycle and migrate from the intestine into the lungs and other organs, such as the liver, heart, and CNS, causing a fulminating, often fatal infection. Shortness of breath and coughing are common symptoms in

this group of patients. Fig. 28.72 is a Gram-stained smear of aspirated sputum showing coiled nematode larvae (arrows), the morphology of which is consistent with *S. stercoralis*.

Most infections in organ transplant recipients are caused by reactivation of latent or chronic infection, although some cases may result from primary infection. Individuals undergoing transplantation and who have a history of travel to or residence in endemic areas may need to be screened for *S. stercoralis*. Secondary bacterial infections that occur because of massive larval migration may be seen in up to 40% of patients with disseminated strongyloidiasis and can delay diagnosis of the underlying infection. The mortality rate in immunocompromised patients is over 80%; the usual causes of death are complications resulting in respiratory failure. Disseminated strongyloidiasis, however, is not common in patients with advanced AIDS, despite their immunocompromised status. Research into this seeming contradiction has shown that progression from intestinal to hyperinfection is dependent on an intact mucosal immune response that allows rhabditiform larvae to develop into infectious larvae in the gut leading to autoinfection. It is hypothesized that immune suppression in HIV prevents the development of the larvae in the gut, and autoinfection is halted.

The life cycle of *S. stercoralis* can take one of three phases (Fig. 28.73): (1) direct, which is similar to that of the

Fig. 28.70 Hookworm egg (unstained, ×400).

Fig. 28.72 Aspirated sputum, Gram stain, light microscopy, (×200). Coiled nematode larvae (arrows). Morphology consistent with *Strongyloides stercoralis*.

Fig. 28.71 A, Hookworm rhabditiform larva. Note the long buccal capsule and lack of prominent genital primordium (iodine wet mount, ×200). B, Hookworm rhabditiform larva, buccal capsule (iodine wet mount, ×200).

Fig. 28.73 Life cycle of *Strongyloides stercoralis*.

hookworm; (2) indirect, which involves a free-living phase; or (3) autoinfection. In the direct life cycle, the fertile egg hatches in the intestine and develops into the rhabditiform larva (noninfective form), which is passed in feces. In the soil, the rhabditiform larvae develop into filariform larvae, which are infective for humans by direct penetration. Once the larva has penetrated skin, it enters the blood circulation, breaks out from the capillaries in the lung, migrates up the bronchial tree and over the epiglottis, and enters the digestive tract, where it matures into the adult worm.

In the indirect life cycle, the rhabditiform larvae in the soil develop into free-living males and into females that produce eggs. At any point, the free-living cycle may revert and result in the production of infective filariform larvae. In most individuals, the autoinfective life cycle allows the initial infection to persist at low levels for years and is the underlying cause of hyperinfection. In this cycle, the rhabditiform larvae develop into the filariform larvae in the intestine rather than being passed in feces. These filariform larvae then penetrate the mucosa, enter the blood circulation, and return to the intestine to develop into adults.

The parasitic female threadworm is small (2.5 mm) and rarely seen in a stool specimen. No male has been identified in intestinal infections. The primary diagnostic stage in humans is the rhabditiform larva. It is 200 to 250 μm long, with a short buccal capsule (Fig. 28.74A), large bulb in the esophagus, and

prominent genital primordium located in its posterior half to posterior third (see Fig. 28.74B). The egg, which is rarely seen except in cases of severe diarrhea, resembles that of a hookworm. It is thin shelled, measures $54 \times 32 \mu\text{m}$, and often is segmented.

The filariform larva has a notched tail, is 500 μm long, and has an esophageal-to-intestinal ratio of 1:1. **Filariform larvae** may be identified in the sputum of patients with hyperinfection (Fig. 28.72). Fig. 28.75 shows a sheep blood agar plate inoculated with sputum, after 24-hour incubation with 5% carbon dioxide in air. Note heavy bacterial growth in the area of primary inoculation. The thin trails of colonies (arrows) lacking the surface of the agar are due to motile larvae. If clinical symptoms suggest *Strongyloides* infection but multiple stool specimens test negative for the larvae, a duodenal aspirate or biopsy specimen may be used for diagnosis because the organism lives in the upper small intestine.

There are no antigen-specific tests for *Strongyloides* infection, and diagnosis relies on identification of the larvae in stool. Antibody tests cannot distinguish current infection from past infection and are prone to yielding false-positive results in infections with other helminths. Ivermectin is the recommended therapy with albendazole used as an alternative. In hyperinfection or disseminated infections, it is recommended that immunosuppressive therapy be reduced if possible.

Fig. 28.74 **A**, *Strongyloides stercoralis* rhabditiform larva, buccal capsule (iodine wet mount, $\times 200$). **B**, *S. stercoralis* rhabditiform larva. Note the short buccal capsule and prominent genital primordium (unstained, $\times 200$).

Fig. 28.75 Sheep blood agar plate inoculated with expectorated sputum, 24-hour incubation with 5% carbon dioxide in air. Note heavy bacterial growth in the area of primary inoculation with thin trails of colonies (arrows) lacing the surface of the agar (see Fig. 28.72).

Fig. 28.76 *Trichinella spiralis* larva (biopsy specimen) (hematoxylin and eosin stain, $\times 200$).

Blood and tissue roundworm infections

Trichinella spiralis

Trichinosis is the infection of muscle tissue with the larval form of *T. spiralis*, a helminth whose adult stages live in the human intestine. Humans acquire the infection by eating undercooked meat, particularly pork that contains the larval forms. In recent years, ingestion of wild game has led to infection by other species of *Trichinella*. The larvae are released from the tissue capsule in the intestine and mature into adults. The female produces liveborn larvae that penetrate the intestinal wall, enter the circulation, and are carried throughout the body. Once the larvae enter the striated muscle, they begin a maturation cycle that is completed in about 1 month. The larvae coil and become encapsulated. Although larvae remain viable for many years, eventually the capsules calcify, and the larvae die.

During the intestinal phase, infected individuals have few symptoms, although diarrhea and abdominal discomfort may be present. Most symptoms occur during the migration and encapsulation periods; the severity of symptoms depends on the number of parasites, the tissues invaded, and the person's general health. Symptoms that occur during the larval phase are the result of an intense inflammatory response by the host.

Common symptoms include periorbital edema, fever, muscular pain or tenderness, headache, and general weakness. Muscle enzyme levels may be elevated. Splinter hemorrhages beneath the nails can be seen in many patients. A 40% to 80% increase in the number of eosinophils is common. Patients with symptoms should be treated with analgesics and general supportive measures. Steroids are given only in rare cases. The use of albendazole or mebendazole is effective when administered early in the infection, before the release of larvae. If diagnosis is delayed, the impact of antiparasitic drugs is less effective.

Because it is difficult to recover adults or larvae in a stool specimen, the diagnosis is often based on clinical symptoms and the patient's history. Biopsy of muscle tissue and identification of the encapsulated, coiled larva is the definitive diagnostic method. Fig. 28.76 shows a biopsy specimen of a muscle containing a larva of *T. spiralis*. Specimens from large muscles, such as the deltoid and gastrocnemius, should be stained for histologic examination (Fig. 28.77). The presence of calcified larvae on a radiographic film indicates infection. Serologic tests are available.

Larva migrans

Two forms of larva migrans exist in humans: cutaneous (creeping eruption) and visceral. In both cases, humans are the accidental host for nonhuman nematode larvae that are unable to

Fig. 28.77 Muscle tissue, directly viewed. Encysted calcified larvae (arrow). Morphology consistent with *Trichinella spiralis*.

complete their life cycle in humans. In the United States, cutaneous larva migrans occurs primarily in the Southwest, Mid-Atlantic, and Gulf Coast areas, and it is most commonly caused by the filariform larva of the dog or cat hookworm (*Ancylostoma braziliense*). The larva penetrates skin through a hair follicle, a break in skin, or unbroken skin. Once inside the body, it does not enter the circulation but wanders through the subcutaneous tissue, creating long, winding tunnels. Secretions from the larva create a severe allergic reaction, with intensely itchy skin lesions that are vesicular and erythematous. Secondary bacterial infections can result from scratching. The infection resolves within several weeks when the larva dies. Diagnosis is based primarily on history and clinical symptoms.

In visceral larva migrans, a human accidentally ingests the eggs of the dog roundworm (*Toxocara canis*) or cat roundworm (*Toxocara cati*). The larvae hatch in the intestine, penetrate the intestinal mucosa, and wander through the abdominal cavity and can enter the lung, eye, liver, or brain. The infection is seen primarily in children 1 to 4 years of age. Clinical symptoms include malaise, fever, pneumonitis, and hepatomegaly. An increase in the number of eosinophils ranging from 30% to 50% and as high as 85% has been reported. CNS complications may develop. Eye invasion is referred to as *ocular larva migrans*, and in these cases, eosinophilia is usually absent. The diagnosis is made on the basis of clinical findings and results of serologic tests using *Toxocara*-specific antigens.

Filarial worms

Filarial worms are roundworms of blood and tissue found primarily in tropical areas of the world. At least eight species infect humans. Those considered most pathogenic are *Brugia malayi*, *Wuchereria bancrofti*, *Onchocerca volvulus*, and *Loa loa*. Lymphatic filariasis (caused by *W. bancrofti*, *B. malayi*, and *Brugia timori*) is the second most common mosquito-borne disease, after malaria. In addition, the nonpathogens *Mansonella ozzardi*, *Mansonella perstans*, and *Mansonella streptocerca* may be seen in clinical specimens. *W. bancrofti* is the most common species and has the greatest geographic distribution being found throughout the tropics and subtropics.

The adult filarial worms give birth to liveborn larvae referred to as *microfilariae*. Identification of the various species depends on the morphology of the microfilaria, periodicity (microfilaria migration), and location of the worms in

the host. Important microfilaria morphologic characteristics include the presence or absence of a sheath (the remnant of the egg from which the larva hatched) and the presence and arrangement of nuclei in the tail. Table 28.10 compares the species of microfilariae commonly found in humans.

Adult worms, which may range in size from 2 to 50 cm, live in human lymphatics, muscles, or connective tissues. Mature females produce microfilariae that are the infective stage for the insect during the insect's blood meal. Once ingested, microfilariae penetrate the insect's gut wall and develop into infective third-stage (filariform) larvae. These larvae enter the insect proboscis and are introduced into human circulation when the insect feeds. Fig. 28.78 illustrates a generalized life cycle for microfilariae.

Wuchereria bancrofti

W. bancrofti is the causative agent of bancroftian filariasis and elephantiasis. Several genera/species of mosquito serve as the insect vector. The adult filarial worm lives in the lymphatics and lymph nodes, especially those in the lower extremities. The presence of the adults initiates an immunologic response consisting of cellular reactions, edema, and hyperplasia. A strong granulomatous reaction with production of fibrous tissue around dead worms ensues. The resulting reaction causes the small lymphatics to become narrowed or closed, causing increased hydrostatic pressure, with subsequent leakage of fluid into the surrounding tissue. During this period, the patient may experience generalized symptoms, such as fever, headache, and chills, as well as localized swelling, redness, and lymphangitis, primarily at sites in the male and female genitalia and extremities. Elephantiasis, a debilitating and deforming complication, occurs in less than 10% of infections, usually after many years of continual filarial infection. Chronic obstruction to the lymphatic flow results in lymphatic varices, fibrosis, and proliferation of dermal and connective tissue. The enlarged areas eventually develop a hard, leathery appearance.

Diagnosis of *W. bancrofti* should include the examination of a blood specimen obtained at night (10 PM to 2 AM) for the presence of microfilariae. Blood specimens may be examined immediately for live microfilariae or may be pooled on a slide and stained. Filtration of up to 5 mL of blood through a 5- μ m nucleopore filter can detect light infections. The microfilariae of *W. bancrofti* are sheathed, and the nuclei do not extend to the tip of the tail (Fig. 28.79). Three antigen detection assays are available, but none have U.S. FDA approval. No antibody detection tests are available.

Brugia malayi

B. malayi, another nocturnal microfilarial species, is limited to the Far East, including Korea, China, and the Philippines. Mosquitoes of the genera *Mansonia* and *Aedes* have been shown to transmit the organism. The pathologic aspects of the disease and the clinical symptoms are the same as those seen with *W. bancrofti* infections. The distinguishing characteristics of the microfilariae are the presence of a sheath and the arrangement of tail nuclei—the nuclei extend to the tip, but a space separates the two terminal nuclei.

Loa loa

Infection with *L. loa*, the eye worm, is limited to the African equatorial rainforest, where the fly vector (*Chrysops*) breeds. Adult worms, which may live for as long as 15 years in

Table 28.10 Comparisons of microfilariae

Organism	Arthropod vector	Periodicity	Location of adult, microfilaria	Tail morphology
<i>Wuchereria bancrofti</i>	Mosquito (<i>Culex</i> , <i>Aedes</i> , <i>Anopheles</i> spp. and others)	Nocturnal	Lymphatics, blood	Sheathed Nuclei do not extend to tip of tail
<i>Brugia malayi</i>	Mosquito (<i>Aedes</i> , <i>Mansonia</i> spp.)	Nocturnal	Lymphatics, blood	Sheathed Terminal nuclei separated
<i>Loa loa</i>	Fly (<i>Chrysops</i> sp.)	Diurnal	Subcutaneous tissue, blood	Sheathed Nuclei extend to tip of tail
<i>Onchocerca volvulus</i>	Fly (<i>Simulium</i> sp.)	Nonperiodic	Subcutaneous nodule, subcutaneous tissue	Unsheathed Nuclei do not extend to tip of tail
<i>Mansonella ozzardi</i>	Midge (<i>Culicoides</i> sp.)	Nonperiodic	Body cavity, blood, skin	Unsheathed Nuclei do not extend to tip of tail
<i>Mansonella perstans</i>	Midge (<i>Culicoides</i> sp.)	Nonperiodic	Mesentery, blood	Unsheathed Nuclei extend to blunt tip of tail
<i>Mansonella streptocerca</i>	Midge (<i>Culicoides</i> sp.)	Nonperiodic	Subcutaneous, skin	Unsheathed Nuclei extend to tip of hooked tail

humans, migrate through the subcutaneous tissue, causing temporary inflammatory reactions called *Calabar swellings*. These characteristic swellings can cause pain and pruritus that last about 1 week before disappearing, only to reappear in another part of the body. The adult worm can often be seen as it migrates across the surface of the eye. Diagnosis can be based on the presence of Calabar swellings or of the adult worm in the conjunctiva of the eye. Microfilariae may be seen in a blood specimen if it is taken during the day, especially around noon, when migration peaks. The microfilaria is sheathed, and nuclei extend to the tip of the tail.

Onchocerca volvulus

Infection with *O. volvulus* is referred to as *onchocercosis*, or *river blindness*. The organism can be found in Africa and South and Central America; transmission occurs by the bite of the black fly (*Simulium*). Adult worms are encapsulated in fibrous tumors in the subcutaneous tissues of humans. Microfilariae can be isolated from the subcutaneous tissue, skin, and the nodule itself, but are rarely found in blood or lymphatic fluid. The nodules in which adults live may measure up to 25 mm and can be found on most parts of the body. They are the result of an inflammatory and granulomatous reaction around the adult worms. Fig. 28.80 depicts a cross-section of

tissue containing these organisms. Blindness, the most serious complication, results when microfilariae collect in the cornea and iris, causing hemorrhage, keratitis, and atrophy of the iris. The presence of endosymbiotic bacteria of the genus *Wolbachia* has been linked to stimulation of the host immune response and may contribute to the inflammatory tissue reaction.

Diagnosis involves clinical symptoms, such as the presence of nodules, and microscopic identification of microfilariae. The diagnostic method used is the *skin snip*, in which a small slice of skin is obtained and placed on a saline mount. Microfilariae with no sheath and with nuclei that do not extend into the tip of the tail are characteristic of this organism. Because the skin snip is painful and poses a risk of infection, researchers are trying to develop alternate diagnostic methods. NAATs are being used in research laboratories. In addition, serologic assays using recombinant antigens have demonstrated high sensitivity and specificity.

Mansonella spp.

M. ozzardi, *M. streptocerca*, and *M. perstans* are filarial worms not usually associated with serious infections. They are transmitted by midges belonging to the genus *Culicoides*. The microfilariae of *M. streptocerca* are found in skin.

Fig. 28.78 Generalized life cycle of microfilariae.

Fig. 28.79 *Wuchereria bancrofti* microfilaria. Note the faintly staining sheath extend from both ends of organism (Giemsa stain, $\times 1000$).

Fig. 28.80 Cross-section of tissue infected with *Onchocerca volvulus* (hematoxylin and eosin stain, $\times 100$).

They are unsheathed and have nuclei that extend to the end of the so-called *shepherd's crook tail*. Microfilariae of *M. ozzardi* and *M. perstans* are found in blood as unsheathed organisms. *M. ozzardi* microfilariae have tails with nuclei that do not extend to the tips, whereas the nuclei in the tail of an *M. perstans* microfilaria extend to the tip.

Dracunculus medinensis

D. medinensis, known as the *guinea worm* (also called the *fiery serpent* of the Israelites described in the Bible), historically

caused serious infections in the Middle East, parts of Africa, and India. It is often found in areas where step-down wells are used. Several health agencies, including the WHO and the United Nations Children's Fund, launched an eradication program in 1986. At that time, an estimated 3.5 million people were infected. By 2012, only 542 cases were reported, and dracunculiasis was limited to four African countries. In 2020, only 27 cases were reported, raising hopes that the disease may be totally eradicated.

Adult worms mature in the deep connective tissue, and the gravid females migrate to the subcutaneous tissue. Initially, a

painful, blisterlike, inflammatory papule appears on the leg in the area where the gravid female is present. The papule ulcerates, and when the person's body comes in contact with water, the female worm exposes her uterus through the ulceration and releases larvae into the water. Patients may experience nausea and vomiting, urticaria, and dyspnea before the rupture of the worm's uterus. If the worm is broken during an attempt to remove it, the patient may experience a severe inflammatory reaction and secondary bacterial infection.

Humans acquire the infection by ingesting a copepod (*cyclops*) that contains an infective larva. The larva is released in the intestine, penetrates the intestinal wall, and migrates to the body cavity, in which males and females mature. When mature and gravid, the female migrates through the subcutaneous tissue to the arm or leg to release liveborn larvae into the water. The rhabditiform larvae are then ingested by the copepod.

The diagnosis is made from the typical appearance of the lesion. Although organism-specific antibodies develop with infection, immunity does not develop, and an individual can be infected multiple times. Treatment is based on the extraction of the adult worm. The worm can be wound around a stick and eased out a few centimeters each day. Analgesics and topical agents, such as metronidazole or thiabendazole, can help in the removal process, although they do not kill the adult worm. Because this method can rupture the worm, surgical excision is preferred.

POINTS TO REMEMBER

- Protozoan cysts, helminth eggs, and helminth larvae can be identified on a wet mount preparation of a fecal concentrate. The identification of protozoan trophozoites and cysts is confirmed on a permanently stained smear.
- Rapid diagnostic tests based on antigen detection (e.g., immunochromatographic) are routinely used for detection of *Giardia duodenalis*, *Cryptosporidium* spp., and *Entamoeba histolytica*.
- Multiplex nucleic acid assays for intestinal pathogens include several organisms—usually including the parasites *G. intestinalis*, *Cryptosporidium* spp., and *E. histolytica*.
- Fecal-oral transmission is the route of infection for enteric protozoa. The cyst is the infective stage, and the trophozoite is the stage that divides and causes tissue damage.
- The major intestinal protozoan pathogens include *E. histolytica* and *G. duodenalis*. *D. fragilis* and *B. hominis* cause symptomatic infections in some patients. There are several commensal protozoa that must be differentiated from the pathogens to ensure appropriate therapy when necessary.
- *E. histolytica*, *E. dispar*, *E. moshkovskii*, and *E. bangladeshi* are morphologically identical, and specific immunoassay techniques must be performed to differentiate the pathogenic *E. histolytica* from the other three nonpathogenic species. If ingested RBCs are present in the trophozoite, the organism can be reported as *E. histolytica*.
- *N. fowleri*, *Acanthamoeba* spp., and *B. mandrillaris* are free-living amebae that can infect humans. *N. fowleri* causes PAM, which is rapidly fatal. *Acanthamoeba* spp. cause keratitis, skin infections, or granulomatous amebic encephalitis, whereas *B. mandrillaris* is associated with GAE and skin infections.
- The genera *Leishmania* and *Trypanosoma* are blood flagellates of humans transmitted by insect bites.
- Human malaria can be caused by five different *Plasmodium* spp.: *P. vivax*, *P. ovale*, *P. malariae*, *P. falciparum*, and *P. knowlesi*. *P. vivax* is the most prevalent.
- The life cycle of malaria is complex, with asexual reproduction taking place in human RBCs (intermediate host) and sexual reproduction occurring in the gut of the mosquito (definitive host).
- Identification of *Plasmodium* spp. is made by observing characteristics of the infected RBCs and the malarial organism on a Wright- or Giemsa-stained peripheral blood smear.
- One rapid diagnostic test (*P. vivax* and *P. falciparum*) is approved for use in the United States for diagnosing malaria. Microscopic confirmation is still performed.
- *B. microti*, an intraerythrocytic parasite, morphologically resembles *P. falciparum* on blood smears.
- The intestinal Apicomplexa species includes *C. parvum*, *C. belli*, and *C. cayetanensis*; the infective stage for humans is the acid-fast–positive oocyst.
- The microsporidia are small intracellular organisms that can infect the gastrointestinal tract and other tissue. Even though they are classified as fungi, the microsporidia are often discussed with eucaryotic parasites because of their morphology and pathogenesis.
- *T. gondii* causes a tissue infection that is usually asymptomatic in immunocompetent hosts. In patients with AIDS, a latent infection can reactivate and cause encephalitis or pneumonia. Congenital transmission can result in serious complications.
- For most flukes, diagnosis is made by finding the egg in a fecal specimen. In the case of the lung fluke (*P. westermani*), the egg may be found in sputum; in the case of *S. haematobium*, the egg is found in urine.
- Humans are the definitive hosts, and animals or insects serve as intermediate hosts for most tapeworms infecting humans.
- Eggs of the beef tapeworm, *T. saginata*, and eggs of the pork tapeworm, *T. solium*, are identical and must be reported as *Taenia* sp.
- The diagnostic stage for a roundworm may be an egg or a larval form, depending on the species.
- Pinworm (*E. vermicularis*) infection is common in children and is diagnosed by finding eggs on a cellophane tape preparation or pinworm paddle. Eggs are laid on the perianal area when the female migrates out through the anus at night.
- Human hookworm infections are generally caused by *N. americanus* and *A. duodenale*. Recently, a third species (*A. ceyanicum*) pathogenic for humans was identified. The eggs are identical and are reported as “hookworm eggs.”
- Eggs of *S. stercoralis* are not usually present in the stool; the typical diagnostic stage is the rhabditiform larva.
- *T. spiralis* is acquired when humans ingest raw or undercooked pork containing the larval form. Diagnosis of trichinosis is made through biopsy of tissue to identify the coiled larval stage.
- Diagnosis of filarial worm infection is made by observing the microfilariae in blood or tissue specimens. Larval characteristics include the presence or absence of a sheath and the location and arrangement of nuclei in the tail of the microfilariae.

LEARNING ASSESSMENT QUESTIONS

- A trichrome-stained smear of a patient's fecal specimen shows the presence of cysts that are oval and approximately 11 μm in size and have four nuclei containing large karyosomes with no peripheral chromatin and a cluttered appearance in the cytoplasm. What is the most likely identification of the organism? Is the organism considered a pathogen?
- A patient with a history of travel to Africa has fever and chills. The physician suspects malaria and orders a blood smear for examination. Why should you do both a thin film and a thick film? Why would final species identification be made from the thin smear?
- Give the major characteristics (including size) that you would use to identify eggs of the following organisms: *Taenia* spp., *Ascaris lumbricoides*, *Trichuris trichiura*, and hookworm.
- Describe the diagnostic method you would use to detect *Enterobius vermicularis* eggs that would not be used with the other types of eggs of intestinal helminths. Explain your answer.
- Describe the microscopic characteristics you would use to differentiate the oocysts of *Cyclospora cayetanensis* and *Cryptosporidium parvum*. Include size, appearance on routine wet mount or trichrome stain, and appearance with special stains.
- You identify a trophozoite that is approximately 22 μm in diameter on a trichrome-stained smear of a stool sample. There is a single nucleus that shows even peripheral chromatin and a small central karyosome. The cytoplasm is relatively clean, but ingested red blood cells are seen. What is the most likely identification of the organism? Is the organism considered a pathogen? If yes, describe the typical patient symptoms and possible complications.
- For both *Cryptosporidium* spp. and *Strongyloides stercoralis*, explain the mechanism of autoinfection in the life cycle and why this phase contributes to increased severity of infection.
- You are examining a blood smear and find an extracellular structure that is approximately 18 μm long. It is tapered at both ends and has an anterior flagellum. An undulating membrane extends the length of the body. What is the genus of this organism? What is the morphologic stage of this organism? With which two diseases do you see this stage in blood?
- Compare primary amebic meningoencephalitis and granulomatous amebic encephalitis. Include the following in your discussion: causative organism, population usually infected, route of infection, clinical symptoms, and method of diagnosis.
- For *Toxoplasma gondii*, *Cryptosporidium* spp., and *S. stercoralis*, compare the clinical presentation in the immunocompetent host and in the immunocompromised host.
- Which of the following are remnants of eosinophils in the stool of some patients with an intestinal parasite infection?
 - Ameboma
 - Charcot-Leyden crystals
 - Morulae
 - Weil-Felix granules
- An international male student from Egypt comes to the campus clinic complaining of blood in his urine. A urinalysis reveals an elongated structure that measures about 110 to 170 μm $\times$ 40 to 70 μm in size and has a terminal spine. Which of the following should be suspected?
 - Schistosoma japonicum* egg
 - Trichuris trichiura* egg
 - Schistosoma haematobium* egg
 - Enterobius vermicularis* egg
- A patient with recent history of camping has explosive, foul-smelling, nonbloody diarrhea. An ova and parasite examination of the stool shows oval structures, about 12 $\times$ 8 μm , with four oval nuclei, each with a large central karyosome, midline axonemes, and two median bodies. Which of the following matches this description?
 - Giardia duodenalis* cyst
 - Entamoeba histolytica* cyst
 - Cryptosporidium parvum* oocyst
 - Chilomastix mesnili* cyst
- Several children at a daycare center are having trouble sleeping and are showing increasing signs of restlessness. One child was recently diagnosed with an intestinal parasite, so the parents are informed that other children should be tested. The parasite egg found during examination is described as embryonated, containing a C-shaped larva, oval, colorless, and slightly flattened on one side. It measures approximately 50 to 60 μm $\times$ 20 to 30 μm . Which of the following matches this description?
 - Enterobius vermicularis*
 - Hookworm
 - Ascaris lumbricoides*
 - Trichuris trichiura*
- Although uncommon, which intestinal parasite is known to leave the colon and cause metastatic diseases, especially liver abscesses?
 - Giardia lamblia*
 - Entamoeba histolytica*
 - Cryptosporidium parvum*
 - Microsporidia*
- What is the most commonly identified intestinal protozoan parasite in the United States?
 - Cryptosporidium parvum*
 - Entamoeba histolytica*
 - Giardia duodenalis*
 - Microsporidia*
- This pathogen can be seen in the sputum and bronchoalveolar fluid of patients with a hyperinfestation syndrome. What is the name of this pathogen?
 - Ascaris lumbricoides*
 - Entamoeba histolytica*
 - Giardia duodenalis*
 - Strongyloides stercoralis*
- Which parasite is responsible for causing a form of blindness in West Africa?
 - Whipworm
 - Hookworm
 - Onchocerca volvulus*
 - Wuchereria bancrofti*

19. A corneal scraping from a patient with keratitis is submitted to the laboratory for examination. Which parasite would you look for in this type of clinical sample?
 - a. *Naegleria* sp. trophozoites
 - b. *Acanthamoeba* sp. cysts and trophozoites
 - c. *Trichinella spiralis* larvae
 - d. *Toxoplasma gondii* oocysts
20. While examining a peripheral blood smear stained with Giemsa-Wright stain, the hematologist notices several red blood cells that contain delicate malarial ring-forms. Further examination shows gametocytes that are banana- or crescent-shaped. Which *Plasmodium* sp. demonstrates these characteristics?
 - a. *Plasmodium vivax*
 - b. *Plasmodium malariae*
 - c. *Plasmodium falciparum*
 - d. *Plasmodium ovale*

Clinical virology

Kevin M. McNabb and Vijay Parashar

CHAPTER OUTLINE

Characteristics of viruses, 710

Structure, 710
Taxonomy, 710
Viral replication, 710

Laboratory diagnosis of viral infections, 713

Specimen selection, collection, and transport, 713
Appropriate specimens for maximum recovery, 713
Methods in diagnostic virology, 714

Double-stranded DNA viruses, 718

Adenoviridae, 718
Herpesviridae, 719
Papillomaviridae, 726
Poxviridae, 726

Single-stranded DNA viruses, 727

Parvoviridae, 727

Double-stranded RNA viruses, 728

Reoviridae, 728

Single-stranded RNA viruses, 729

Arenaviridae, 729
Bunyavirales, 729
Caliciviridae, 730
Coronaviridae, 731
Filoviridae, 732
Flaviviridae, 733
Orthomyxoviridae, 734
Paramyxoviridae, 736
Picornaviridae, 738
Retroviridae, 739
Rhabdoviridae, 742
Togaviridae, 742

Hepatitis viruses, 743

Hepatitis A virus, 744
Hepatitis B virus, 744
Hepatitis D virus, 745

Hepatitis C virus, 747
Hepatitis E virus, 748
Other hepatitis viruses, 748

Prions, 749

Treatment and management of viral infections, 749

Antiviral therapy, 749
Vaccines, 749

Bibliography, 751

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the characteristics of viruses and how they differ from bacteria.
2. Describe how viruses replicate.
3. Describe the proper procedures for collection and transport of specimens for viral detection.
4. Name the appropriate specimen for maximum recovery of the suspected viral agent.
5. Compare the different methods used in the diagnosis of viral infections.
6. Explain the advantages and limitations of cell cultures for diagnosing viral infections.
7. Explain the advantages and limitations of rapid viral antigen detection methods.
8. Discuss the indications and limitations of serologic assays in the diagnosis of viral infections.
9. Describe how *cytopathic effect* is used to presumptively identify viral agents.
10. Evaluate the vaccination program for influenza.
11. List common opportunistic infections and other indicators of acquired immunodeficiency syndrome.
12. Create an algorithm for the serologic diagnosis of human immunodeficiency virus infection.
13. Compare the genomes and modes of transmission of the human hepatitis viruses.
14. Develop an algorithm for the serologic diagnosis of viral hepatitis.

15. Interpret the results of a hepatitis serologic profile.
16. For each of the viral agents presented in this chapter, discuss how the virus is transmitted, how the infection is produced, and the most effective method of laboratory diagnosis.
17. Discuss common treatment and prevention strategies for viral infections.

KEY TERMS

Aneuploid	Koplik spots
Antigenic drift	Nucleocapsid
Antigenic shift	Nucleoside reverse transcriptase inhibitors (NRTIs)
Arboviruses	Obligate intracellular parasites
Capsid	Pandemic
Cell cultures	Primary cell cultures
Continuous cell cultures	Prions
Cytopathic effect	Syncytia
Diploid	Tissue culture
Envelope	Vaccinia virus
Hemagglutinin	Virion
Heteroploid	

Case in point

On March 2, 2020, a 65-year-old male patient with a 14-year history of chronic lymphocytic leukemia along with hypogammaglobulinemia, chronic leukocytosis, and severe anemia presented to the emergency department of a local community hospital with lower back, lower hip, and lower extremity pain. He underwent surgery for a hip fracture related to his cancer on March 5, 2020, and was subsequently transferred to a rehabilitation facility. He was readmitted to the hospital for anemia 2 weeks later. A chest x-ray was normal, and other tests were unremarkable. A chest computed tomography (CT) was also unremarkable. The patient had no respiratory or systemic symptoms. He could not return to the rehabilitation center because of a confirmed outbreak of severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) infection, the cause of coronavirus disease 2019 (COVID-19), at the facility. Because he lived in the rehabilitation facility around the time of the COVID-19 outbreak, he was tested and found positive for SARS-CoV-2 on March 25, 2020.

After the SARS-CoV-2 diagnosis, the patient was kept in an isolation unit in a single room with negative air pressure. Because of acquired hypogammaglobulinemia caused by his cancer, the patient received intravenous (IV) immunoglobulin every 4 weeks as part of his treatment regimen. In early May, he was transfused with 200 mL of SARS-CoV-2 convalescent plasma under a U.S. Food and Drug Administration (FDA) emergency investigational new drug protocol. The infection persisted, and 1 week later, he received another 200-mL dose of convalescent plasma from a different donor. Infectious SARS-CoV-2 was successfully cultured from the nasopharyngeal swabs collected on day 35 and day 72. For the next 18 weeks, he was tested for SARS-CoV-2 another 20 times using an in-house real-time reverse-transcription polymerase chain reaction (RT-PCR) test and remained positive through July 16, 2020 (113 days after the initial positive RT-PCR test). Subsequently, he tested negative on six consecutive swabs from July 22 to August 10, indicating that the infection had finally cleared. While the patient remained asymptomatic for the entire duration of his hospitalization, culturable virus was obtained on day 25, day 60, and day 80 of his admission.

Issues to consider

After reading the patient's case history, consider:

- How the patient's medical history affected his viral infection
- What information is obtained from the laboratory, radiograph, and CT results
- Could this patient have been returned to the rehabilitation facility sooner? If yes, why? If no, why not?
- Other testing for SARS-CoV-2 includes antigen testing and testing for immunoglobulin G (IgG) and IgM antibodies. Would the patient's diagnosis or treatment have improved with any of these assays?

Clinical virology continues to be a challenging and exciting area of clinical microbiology. It has evolved over the years from viral diagnostic testing performed in only very few, highly specialized laboratories to being available in many modern laboratories of today. Most of the older, traditional diagnostic methods were time-consuming, cumbersome, and required significant expertise because they were primarily based on cell culture, serology, and microscopy (both bright-field and electron). Often, results were too slow to be clinically useful and were perhaps even irrelevant to the clinician.

With the recent emergence of molecular diagnostic testing for viral infections, detection is much faster, more sensitive, and more specific, resulting in earlier intervention, quicker treatment, and more favorable patient outcomes. The development of increasingly larger molecular panels to detect viral infections from blood, cerebrospinal fluid (CSF), and respiratory samples has made the diagnosis of these infections more clinically useful. Molecular technology is becoming more cost-effective and more common in the routine clinical microbiology laboratory.

Viruses have been ominous clinical threats since documented medical history. Viral infections that begin in local communities as endemic disease could eventually spread globally, leading to pandemics (as we are currently facing with COVID-19) that burst into our daily lives, disrupting all facets of life. The most deadly viral pandemic of the last century was caused by influenza A virus (H1N1) in 1918. This disease, known as the Spanish flu, resulted in at least 500 million infections and 50 million deaths worldwide. There have been several deadly viral pandemics in the last 40 years, including the following:

- The human immunodeficiency virus (HIV), identified as the causative agent of acquired immunodeficiency syndrome (AIDS), was first identified in 1981 and is still causing an ongoing epidemic in many parts of the world. HIV has infected over 79 million people and resulted in 36 million deaths. The development of antiretroviral therapy (ART) has helped to decrease mortality and improve the quality of life of infected individuals.
- The West Nile virus (WNV) was introduced into North America in 1999 and within a few years became endemic to most regions of the United States. In 2012 there was a resurgence, resulting in double the yearly cases seen before that time.
- Dengue virus, the causative agent of dengue fever (DF), is one of the most concerning members of the family Flaviviridae. Spread by mosquito bites, it is emerging as a pandemic in many countries. More than 1 billion people are at risk of dengue infection worldwide.

Brazil has been plagued with outbreaks of DF for over 30 years, and currently over 1 million cases are reported annually.

- The first coronavirus pandemic was caused by severe acute respiratory syndrome coronavirus 1 (SARS-CoV-1). The infections began in late 2002 and spread rapidly worldwide in 2003. Although the mortality rate was high, the global outbreak was quickly contained.
- In 2007, a Zika virus outbreak was reported on the island of Yap (Micronesia), where nearly 75% of the population was infected. In Brazil, a Zika virus outbreak started in November 2015 and continued into 2016 with subsequent spread to the Americas, including the southern United States. In this outbreak, there was a link to microcephaly in neonates.
- Influenza A virus subtype H1N1 (2009) first emerged in Mexico and rapidly spread to other countries, resulting in thousands of deaths worldwide. Since then, several variants of influenza virus subtypes appeared epidemically. One variant, influenza A (H3N2), affected humans and swine throughout the United States and was implicated in infections in visitors to county fairs. The key to control the spread of influenza viruses is to develop new vaccines based on the subtypes identified in the population every year. Annual flu vaccines have been successful in preventing flu pandemic outbreaks.
- Middle East respiratory syndrome coronavirus (MERS-CoV) emerged in Saudi Arabia in 2012 and later spread to 27 countries, resulting in about 2000 cases and 866 deaths.
- The spread of chikungunya virus to Caribbean countries and territories of the United States was first seen in late 2013 and reported in Florida, Puerto Rico, and the U.S. Virgin Islands. Prior to 2013, viral outbreaks were limited to countries in Africa, Asia, Europe, and the Indian and Pacific Oceans.
- In West Africa, an Ebola outbreak started in 2014 and lasted well into 2016. Over 28,000 cases in 10 countries were reported. During the outbreak, 11 patients were treated in the United States. Two cases were travel associated, and two cases involved health care workers caring for one of the patients. An additional 7 patients were transported by chartered aircraft to hospitals for treatment. Additional outbreaks were reported in 2017, 2018, 2020, and 2021.
- SARS-CoV-2 was first identified in China in late 2019 as cases of atypical pneumonia. The infection spread rapidly across the world, leading to global shutdowns and travel restrictions. As of July 2022, the World Health Organization (WHO) reported 544,324,069 confirmed cases of COVID-19, including 6,332,963 deaths (and still counting). The rapid development of effective mRNA-based vaccine against the virus helped to bring a state of some normalcy and decline in mortality, but the virus is still mutating rapidly and the pandemic is far from over.
- In 2022, monkeypox caused outbreaks in several nonendemic countries, including the United States. Sporadic outbreaks of monkeypox virus have been reported in many African countries since 2003. The first outbreak of monkeypox in the United States occurred in 2003. Monkeypox virus is closely related to smallpox virus, and the smallpox vaccine has been effective in preventing monkeypox infections.

Viruses continue to thrive in a small subset of hosts (human and sometimes animal reservoirs) even after a pandemic ends. For example, HIV continues to devastate entire continents, effectively reducing large portions of each generation. Mosquitoes continue to spread dengue virus throughout the world with significant impact. Over the years, there has been a rise in infections by enterovirus 71 (EV71), which has killed hundreds of children throughout parts of the Asian continent. Every year about 5% to 15% of the world's population is infected with influenza virus. Despite influenza surveillance programs, reliable annual vaccines, and dependable antiviral medications, several of these infected individuals develop severe disease. Influenza virus and other viruses lead to hundreds of thousands of deaths globally. This chapter discusses basic virology, including the advances and challenges in clinical virology in the modern clinical laboratory and how the laboratory helps diagnose viral illnesses.

Characteristics of viruses

Structure

All viruses contain nucleic acid and a protein **capsid**, with some viruses having up to 90% of their mass from the protein component. Typically, viruses contain a viral genome of ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). The genome can be double-stranded (ds) or single-stranded (ss). The genome and its protein coat together are referred to as the **nucleocapsid**. The entire virus particle is called the **virion**. Some viruses also have a phospholipid, labile **envelope** surrounding the virion. Enveloped viruses are usually more susceptible to inactivation by high temperature, extreme pH, and chemicals compared with non-enveloped (or naked) viruses. The envelopes are of host origin, derived from the plasma membrane, but contain virus-encoded proteins.

The morphology of virions is helical, polyhedral (e.g., *icosahedral*, a geometric shape with 20 triangular sides), or complex. The envelope masks the shape of the virion, so most enveloped viruses are variably shaped or pleomorphic. The poxviruses are the largest viruses (260 × 450 nm), and the smallest human virus is the poliovirus, which is 25 nm in diameter.

Taxonomy

Originally, viruses were classified by the diseases they caused and their host range. Now, viruses are classified in orders, families, genera, and species based on genome type (RNA or DNA), number of strands in the genome (ds or ss), morphology, and presence or absence of an envelope. Nucleotide sequence is also a valuable tool for the taxonomic placement of viruses. A summary of the clinically significant viruses is shown in [Table 29.1](#).

Viral replication

Viruses are **obligate intracellular parasites**, that is, they must be inside a living cell and use the host cell machinery to replicate. Virions absorbing or attaching to the cell surface is the first step in infecting a cell. The absorption is specific for certain cell receptors via viral *adhesion molecules*. Most host

Table 29.1 List of viruses causing human disease, based on nucleic acid characteristics and taxonomy

Genome strand	Family (subfamily)	Genus	Species
dsDNA	Adenoviridae	<i>Mastadenovirus</i>	<i>Human mastadenoviruses</i> A to G
	Herpesviridae (Alphaherpesvirinae)	<i>Simplexvirus</i>	<i>Human alphaherpesviruses</i> 1 and 2, macacine herpesvirus 1 (B virus)
		<i>Varicellovirus</i>	<i>Human alphaherpesvirus</i> 3 (varicella-zoster virus)
	(Betaherpesvirinae)	<i>Cytomegalovirus</i>	<i>Human betaherpesvirus</i> 5 (cytomegalovirus)

Table 29.1 List of viruses causing human disease, based on nucleic acid characteristics and taxonomy—cont'd

Genome strand	Family (subfamily)	Genus	Species
	Coronaviridae (Coronavirinae)	<i>Alphacoronavirus</i>	<i>Human coronavirus 229E, human coronavirus NL63</i>
		<i>Betacoronavirus</i>	<i>Betacoronavirus 1, human coronavirus HKU1, human coronavirus OC43, MERS-related coronavirus, SARS-related coronavirus</i>
	(Torovirinae)	<i>Torovirus</i>	<i>Human torovirus</i>
	Filoviridae	<i>Marburgvirus</i>	Marburg marburgvirus, Ravn virus
		<i>Ebolavirus</i>	Zaire ebolavirus, Tai Forest ebolavirus, Reston ebolavirus, Sudan ebolavirus, Bundibugyo ebolavirus
	Flaviviridae	<i>Flavivirus</i>	<i>Yellow fever virus, West Nile virus, Dengue virus, Zika virus, Japanese encephalitis virus, Langat virus, Murray Valley encephalitis virus, Omsk hemorrhagic fever virus, Powassan virus, St. Louis encephalitis virus, Tick-borne encephalitis virus</i>
		<i>Hepacivirus</i>	<i>Hepacivirus C (hepatitis C virus)</i>
	Hepeviridae	<i>Orthohepevirus</i>	<i>Orthohepevirus A (hepatitis E virus)</i>
	Orthomyxoviridae	<i>Influenzavirus A</i>	<i>Influenza A virus</i>
		<i>Influenzavirus B</i>	<i>Influenza B virus</i>
		<i>Influenzavirus C</i>	<i>Influenza C virus</i>
		<i>Influenzavirus D</i>	<i>Influenza D virus</i>
	Paramyxoviridae	<i>Respirovirus</i>	<i>Human respirovirus 1 and 3 (human parainfluenza viruses 1 and 3)</i>
		<i>Morbillivirus</i>	Measles virus
		<i>Rubulavirus</i>	<i>Human rubulavirus 2 and 4 (human parainfluenza viruses 2 and 4), Mumps rubulavirus</i>
		<i>Henipavirus</i>	Hendra henipavirus, Nipah henipavirus
	Pneumoviridae	<i>Orthopneumovirus</i>	<i>Human orthopneumovirus (human respiratory syncytial virus)</i>
		<i>Metapneumovirus</i>	<i>Human metapneumovirus</i>
	Picornaviridae	<i>Enterovirus</i>	<i>Enterovirus A (includes some coxsackieviruses)</i> <i>Enterovirus B (includes echoviruses and some coxsackieviruses)</i> <i>Enterovirus C (includes polioviruses and some coxsackieviruses)</i> <i>Enterovirus D Rhinovirus A, B, and C</i>
		<i>Parechovirus</i>	<i>Parechovirus A (human parechovirus)</i>
		<i>Hepatovirus</i>	<i>Hepatovirus A (hepatitis A virus)</i>
		<i>Lyssavirus</i>	<i>Rabies lyssavirus</i>
	Rhabdoviridae		
	Retroviridae (Orthoretrovirinae)	<i>Lentivirus</i>	<i>Human immunodeficiency virus 1 and 2</i>
		<i>Deltaretrovirus</i>	<i>Primate T-cell lymphotropic virus 1 and 2</i>
	Togaviridae	<i>Alphavirus</i>	<i>Chikungunya virus, eastern equine encephalitis virus, Venezuelan equine encephalitis virus, western equine encephalitis virus</i>
		<i>Rubivirus</i>	<i>Rubella virus</i>

CoV, Coronavirus; dsDNA, double-stranded deoxyribonucleic acid; MERS, Middle East respiratory syndrome; SARS, severe acute respiratory syndrome; ssDNA, single-stranded deoxyribonucleic acid; ssRNA, single-stranded ribonucleic acid.

cell receptors are glycoproteins, some of which include the immunoglobulin superfamily molecules (for poliovirus), acetylcholine (for rabies virus), sialic acid (for influenza virus), CD4 (for HIV), complement receptor C3d (for Epstein-Barr virus [EBV]), and angiotensin-converting enzyme 2 (for SARS CoV-2). The adhesion molecule receptor interaction determines the viral tissue tropism in the host.

The next step in viral replication is penetration. Viruses can penetrate the cell by several mechanisms. Naked virions can penetrate the cell membrane directly. Enveloped viruses can enter the cell by fusion with the plasma membrane, or by endocytosis, whereby the enveloped virus enters the cell in a cytoplasmic vacuole. Once inside the cell, the virus loses

its protein coat, releasing the genome. This process is called *uncoating*. RNA viruses usually release the genome into the cytoplasm, whereas most DNA viruses release their genome into the host nucleus. The viral genome then directs the host cell to make viral proteins and replicate the viral genome. Depending on the virus, the metabolism of the host cell may be completely stopped (as with polioviruses) or may continue at a reduced scale, as seen with influenza viruses.

The next step is the assembly or maturation of the virus particles. The capsid protein subunits aggregate to form *capsomers*, and the capsomers combine to form the capsid. The capsid and genome associate to form the nucleocapsid. The new virions are then released by lysis if they are

naked viruses or by budding if they are enveloped viruses. During budding, part of the host cell plasma membrane surrounds the viral capsid and becomes the viral envelope.

Laboratory diagnosis of viral infections

Laboratories provide different levels of service, depending on the mission, financial resources, and patient populations. All of these must be balanced to provide the most cost-effective and complete diagnostic methods that meet the needs of the clinical staff. Full-service virology laboratories provide viral culture and identification by using mammalian **cell cultures** to support the growth of viruses in clinical specimens. Although not all clinical diagnostic facilities provide full virology services, laboratories can still provide information about viral infections by utilizing rapid tests that detect specific viruses in clinical specimens. Tests can involve the detection of viral antigens by using methods such as immunofluorescence (IF) or enzyme immunoassay (EIA) and detection of viral RNA or DNA using polymerase chain reaction (PCR) assays.

Low-complexity tests with waivers from the Clinical Laboratory Improvement Act (CLIA) bring viral identification services into physicians' offices and clinics. Some laboratories limit their virology services to *viral serology*—determining the patient's immune response to viruses—rather than detecting viruses directly. Although this is sometimes useful, it usually takes several weeks after infection before these antibodies are produced, which may mean that treatment would be too late or not needed before the diagnosis is made. Molecular methods based on nucleic acid detection and amplification are being used by more clinical laboratories. This technology can detect viral infections very early in infection, and many tests are completed in less than 1 hour. Over the past 10 years, this technology has improved such that larger, more complete syndromic panels are available that can quickly identify infectious agents from many types of specimens to provide a quick, accurate diagnosis of many viral and bacterial infections at once (e.g., multiplex PCR). Since viruses tend to undergo frequent mutations, the molecular test also helps to identify different variants of the same virus to identify the virulent and more dominate strains.

Specimen selection, collection, and transport

Several different clinical specimens are suitable for the diagnosis of viral diseases. The clinical signs and symptoms of diseases often point to the target organ(s) involved, which can help determine the most appropriate specimen(s) to collect. This, combined with a basic understanding of viral pathogenesis, can help in specimen selection for each specific virus. It is important to ensure, however, that the specimen collected can be used to isolate a wide range of viral pathogens because different viruses can have overlapping clinical symptoms.

Since viral shedding is usually greatest during the early stages of infection, the best specimens are those collected as early as possible, which, in many infections, is even before symptoms occur. The sensitivity of viral culture can decrease rapidly 3 days after the acute onset of symptoms, so care must be taken to collect specimens appropriately to maximize detection and identification. Specimens should be collected aseptically.

Depending on the anatomic site and the method of collection, specimens can be sterile or nonsterile (i.e., contaminated with bacteria and/or fungi). This will determine how much specimen processing is required before viral culture. Non-culture-based test methods are typically not affected by contamination, but this varies with the system. In a normally sterile specimen, such as blood, CSF, or tissue, identification of a virus without bacterial isolates usually means that the virus is the cause of the disease.

Nonsterile specimens are obtained from sites that contain normal biota, such as the respiratory tract, genital tract, skin, or stool. These specimens may require processing to reduce contaminants and promote viral growth. Aspirated secretions are often preferable, but swabs are easier to use for collection. Swabs must be made of Dacron or rayon. Calcium alginate swabs inhibit the replication of some viruses and can interfere with nucleic acid amplification tests (NAATs). Tissue samples must be kept moist and must not be placed in transport media unless it is specifically designed for viral preservation. Often it is preferred for tissue specimens to be sent to the laboratory in a sterile container.

Viral transport medium, saline, or trypticase soy broth can be added to sterile containers to keep tissues from drying. Several viral transport media are commercially available, and most consist of a buffered isotonic solution with a protein, such as albumin, gelatin, or serum, to protect more fragile viruses. Often, antibacterial and antifungal agents are added to viral transport media to inhibit contamination by microorganisms. Samples that can be collected with viral transport media are respiratory, swab, and tissue samples. Samples that should be collected without viral transport media include blood, bone marrow, CSF, amniotic fluid, urine, pericardial fluid, and pleural fluid. The transport container should be unbreakable and able to withstand freezing and thawing.

It is optimal to process viral specimens for culture immediately. Some viruses, such as respiratory syncytial virus (RSV), are much more difficult to recover, even a few hours after collection. If specimens cannot be processed immediately after collection, they should be stored at 4 C. Specimens should not be frozen unless a significant delay (>4 days) in processing is anticipated. In this case, specimens should be frozen and held at -70 C. Specimens should never be stored at -20 C because this temperature facilitates the formation of ice crystals that will disrupt the host cells and result in loss of viral viability. Repeated freeze-thaw cycles must be avoided because they can also result in loss of viral viability. Freeze-thaw cycles are less of a problem for molecular testing since nucleic acids are able to withstand temperature changes. As a rule, repeat freeze-thaw cycles should always be avoided and the laboratory scientists must follow the guidelines provided by the manufacturer of the specific test.

Appropriate specimens for maximum recovery

For optimal recovery, specimens for viral isolation should be collected from the affected site. For example, secretions from the respiratory mucosa are most appropriate for viral diagnosis of respiratory infections. Aspirates, or surface swabs, are usually appropriate for lesions. If the intestinal mucosa is involved, a stool specimen is appropriate. However, if systemic, congenital, or generalized disease is involved,

Table 29.2 Tests available for common viral pathogens and specimens for culture

Body system affected	Antigen detection	Virus isolation	Serology	Culture specimens	Molecular testing
Respiratory tract	Adenovirus, coronavirus-2, herpes simplex virus (HSV), cytomegalovirus (CMV), influenza virus types A and B, parainfluenza virus, respiratory syncytial virus (RSV)	Adenovirus, coxsackievirus group A, coxsackievirus group B, echovirus, HSV, CMV, influenza virus types A and B, parainfluenza virus, RSV, reovirus, rhinovirus	Adenovirus, coxsackievirus group A, coxsackievirus group B, echovirus, HSV, CMV, influenza virus types A and B, parainfluenza virus, RSV	Nasal aspirate, nasopharynx (NP) or throat swabs, bronchoalveolar lavage, lung biopsy	Single marker molecular testing available or panels for typical respiratory pathogens available
Gastrointestinal tract	Adenoviruses 40 and 41, rotavirus	Adenoviruses 40 and 41, coxsackievirus group A, reovirus	Adenoviruses 40 and 41, coxsackievirus group A	Stool, rectal swab	Panels for multiple markers available
Liver			Hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), hepatitis E virus (HEV), Epstein-Barr virus (EBV)		
Cutaneous	HSV, adenovirus, varicella-zoster virus (VZV)	HSV, adenovirus, coxsackievirus group A, coxsackievirus group B, echovirus, enterovirus, measles virus, VZV, reovirus, rubella virus, vaccinia virus	HSV, adenovirus, coxsackievirus group B, dengue virus, echovirus, human herpesvirus 6 (HHV-6), measles virus, VZV, parvovirus B19, rubella virus, vaccinia virus	Vesicle aspirate, NP aspirate and stool, lesion swab	Molecular testing is available for HSV-1 and HSV-2
Central nervous system	HSV-1 and HSV-2, mumps virus, CMV, enterovirus, HHV-6, human parechovirus, VZV	Coxsackievirus group A, coxsackievirus group B, echovirus, enterovirus, poliovirus, HSV-1 and HSV-2, mumps virus	Coxsackievirus group A, coxsackievirus group B, echovirus, poliovirus, HSV, HHV-6, mumps virus	Cerebrospinal fluid (CSF), brain biopsy, NP swabs, stool	Molecular panel available for CSF that includes CMV, enterovirus, HSV-1 and HSV-2, HHV-6, human parechovirus, and VZV
Ocular	Adenovirus, HSV	Adenovirus, HSV, coxsackievirus group A, enterovirus	HSV, coxsackie group A	Corneal swabs, conjunctival scrapings	
Genital	HSV	HSV	HSV	Vesicle aspirate, vesicle swab	Molecular testing available for HSV-1 and HSV-2

specimens from multiple sites, including blood (buffy coat), CSF, and the portals of entry (oral or respiratory tract) or exit (urine or stool) are appropriate. For example, enteroviruses that cause respiratory infections could also be recovered from the stool after the respiratory shedding has ceased. In addition, enteroviruses are a major cause of aseptic meningitis and can also be isolated from urine specimens. Table 29.2 lists recommended specimens to be collected for viral diagnosis according to the body site affected. Incorrect or poor specimen collection can result in a false-negative diagnostic result.

Methods in diagnostic virology

The clinical laboratory uses three major methods to diagnose viral infections:

- Direct detection in clinical specimen
 - Microscopy to detect cytopathic effect

- Detection of virus antigens
- Nucleic acid detection
- Isolation of viruses in cell cultures
- Serologic assays to detect antibodies to virus

Each laboratory must decide on the methods to offer based on the spectrum of infections encountered, population of patients served, financial resources, and staffing. In most laboratories, a combination of several methods is used to optimize detection and reduce cost.

Direct detection

In general, direct detection methods are not as sensitive as culture methods but can offer quick results to allow rapid therapy. Many of these tests can be performed in a few minutes. Viral detection allows clinicians to make relevant decisions about therapy, infection control measures, and

hospitalization. In many cases, virology results may be available before routine bacteriology culture results are.

Microscopy

Because of their extremely small size, bright-field light microscopy is not useful for visualizing viruses. The poxviruses, however, are the largest of the human viruses (about the size of chlamydiae) and can be seen. Electron microscopy has a greater magnification and can be used to visualize virions, and it is useful to detect nonculturable viruses, such as Norwalk virus, in stool filtrates. However, electron microscopy is expensive, labor-intensive, and not a very sensitive method of detecting viruses. Therefore electron microscopy is rarely used in clinical laboratories and is more suited for large teaching or research institutions.

Many viruses produce distinctive visual changes in infected cells referred to as a **cytopathic effect (CPE)**. Although virus particles cannot be visualized, the CPE can be detected in cells collected from infected sites with bright-field microscopy. The most common method used is the Tzanck smear, which is the scraping of an ulcer base to look for Tzanck cells. Tzanck cells are large round keratinocytes that are degenerated as a result of viral infection. A Tzanck smear can detect Cowdry type A bodies from herpes simplex virus (HSV) and varicella-zoster virus (VZV) lesions. Papanicolaou (Pap) smears can reveal human papillomavirus (HPV)-associated koilocytes, which are squamous cells with an enlarged nucleus surrounded by a nonstaining halo. Rabies is sometimes diagnosed by detecting Negri bodies, which are eosinophilic cytoplasmic inclusions in neurons. However, this is an insensitive method for diagnosing rabies.

Antigen detection

IF can be a valuable tool to detect viral antigens in clinical specimens. Fluorophore-labeled antibodies against viral antigens allow direct visualization of viruses and infected cells, and some tests can amplify signals, which enhance sensitivity. In the direct fluorescent antibody (DFA) tests, cells from a patient are fixed to a microscope slide, and fluorescence-labeled antibodies are added. If viral antigens are present in the sample, the labeled antibody will bind, and fluorescence will be seen using fluorescent microscopy (see [Chapter 10](#) for a more detailed description). This test is reasonably easy to

perform and is highly specific, and can be completed in 2 to 6 hours. DFA assays are available for numerous viruses, including adenovirus, influenza A and B viruses, measles virus, parainfluenza viruses (PIVs) 1 to 4, and respiratory syncytial virus (RSV) from respiratory specimens; herpes simplex virus (HSV)-1, HSV-2, and varicella zoster virus (VZV) from cutaneous lesion material; and cytomegalovirus (CMV) from blood. The key caveat is cross-reactivity of closely related viruses to the antibodies used. Therefore it can be difficult to precisely identify the viral strain using DFA.

Many EIA tests for viral antigen detection are commercially available, and most use multi-well microtiter plate formats, which offer variable testing capacity to meet the needs of small or large laboratories. These tests can detect RSV and influenza A virus from respiratory specimens, hepatitis B virus (HBV) and HIV-1 from serum or plasma, enteric adenoviruses from feces, and HSV from cutaneous lesions and conjunctival swabs. Other tests are packaged in single-test platforms, with positive specimens detected by colorimetric or optical density changes on membrane or silicon surfaces ([Fig. 29.1](#)). Often the biggest problem with this testing is in the interpretation of a color change or the detection of a line. Some vendors now supply optical readers for these types of assays to help standardize interpretation of the results.

EIA is often less sensitive than cell cultures or IF, so negative results are confirmed with cell culture, IF, or nucleic acid-based tests. These assays are the most popular viral testing methods in hospital-based laboratories, but most EIA testing will likely be replaced by nucleic acid-based detection as it continues to become cheaper, is easier to perform, and offers the ability to detect multiple viruses simultaneously (multiplex testing).

Nucleic acid-based detection

Nucleic acid-based detection assays have shifted the focus of clinical virology. Not only can the presence or absence of a virus be determined with nucleic acid-based analysis but, depending on the assay used, a quantitative result can also be obtained. Advantages of nucleic acid-based detection assays include a much faster turnaround time (TAT); better sensitivity compared with cell culture and DFA; assays that can be quantitative; detection of nonculturable viruses such as norovirus (NoV) and hepatitis viruses; multiplex testing; and

Fig. 29.1 A, Card format rapid immunochromatographic membrane assay, BinaxNOW (Abbott Laboratories, Chicago, IL), for three common respiratory viruses: influenza A and B and respiratory syncytial virus. B, Examples of positive and negative results.

potentially genetic characterization of the virus (genotype). Overall, molecular assays lead to faster treatment and more favorable patient outcomes. Disadvantages include detection of both active and inactivated virus, higher cost, need for specialized training and more complex facilities, and lack of assays approved by the FDA. Smaller clinical laboratories often rely on sending these tests to reference laboratories at a higher cost and longer TAT.

Examples of nucleic acid–based assays include the polymerase chain reaction (PCR) and reverse transcription-PCR (RT-PCR) assays; branched DNA assay; nucleic acid sequence–based amplification (NASBA); and a combination of PCR and flow cytometry, such as the Luminex system (Luminex Molecular Diagnostics, Austin, TX) for multiplex detection. Nucleic acid hybridization assays can detect viruses from various clinical specimens. Assays are available to detect many viruses, including HPV from endocervical specimens, and classify them into types that have a high risk or a low risk for cancer. Other hybridization tests can detect CMV from blood and HBV from plasma and serum.

Numerous gene amplification techniques are available for detection of viral genomes, primarily bloodborne pathogens, such as HIV-1, HBV, hepatitis C virus (HCV), and WNV. With a dramatic increase in the incidence of West Nile fever in the United States, there has been an increased demand for WNV testing by PCR. Detection of influenza A virus by PCR assay was shown to be not only more sensitive than traditional cell culture and shell vial methods, but it also allowed earlier administration of antiviral therapy to patients, resulting in more favorable patient outcomes. A microarray assay for rapid subtyping of influenza A virus isolates is available and would be valuable in an outbreak or pandemic.

A Luminex assay to detect and type or subtype 20 different viral pathogens within 5 hours has also been described. These types of systems help epidemiologists, infectious disease physicians, and others in the public health community by rapidly identifying viral pathogens during an outbreak. Newer isothermal nucleic acid amplification technology is now becoming more prevalent (Alere, Waltham, MA); it does not require temperature cycling and can deliver results in as soon as 20 minutes with vast performance improvement over slower PCR-based assays.

In the case of global pandemics, rapid and continuous monitoring is of utmost importance. For example, a number of nucleic acid–based assays were deployed to monitor the spread of COVID-19. These include quantitative real-time PCR assays, which provide results in 2 to 3 hours, as well as isothermal assays such as the Abbott assay, which can provide a result within 5 minutes. With the emergence of mutations, it is desirable to screen for multiple variants of virus in a single assay. Several multiplex assay systems have been developed. For example, Cepheid's GenXpert, which identifies several viruses including Zika, Ebola, SARS-COV-2, and others, is widely used in clinical laboratories for a rapid and automated way of screening a large number of samples.

Isolation of viruses in cell cultures

In clinical virology, isolating viruses is still the “gold standard” against which all other methods are compared. Three methods are used for the isolation of viruses in diagnostic virology:

cell culture, animal inoculation, and embryonated eggs. The method most commonly used by clinical virology laboratories is cell culture. Animal inoculation is extremely costly and used only as a special resource in reference or research laboratories. For example, certain coxsackie A viruses require suckling mice for isolation of the virus. Embryonated eggs are rarely used; isolation of influenza viruses is enhanced in embryonated eggs, but this is accomplished more easily in cell culture.

Establishing at least a limited clinical virus isolation capability in routine laboratories can be justified, provided qualified personnel and space are available. Most of the clinical workload is for the detection of HSV in genital specimens and respiratory viruses. A significant number of common clinical viruses can often be identified within 48 hours of inoculation, including HSV, influenza A and B viruses, PIVs 1 to 4, RSV, adenovirus, and many enteroviruses.

Cell culture

The term *cell culture* is technically used to indicate culture of cells *in vitro*; the cells are not organized into a tissue. The term **tissue culture** or *organ culture* is used to denote the growth of tissues or an organ so that the architecture or function of the tissue or organ is preserved. Many clinical virologists use these terms interchangeably; however, *cell culture* is the correct term.

Cell cultures can be divided into three categories based on their longevity in cultures: primary, low passage (or finite), and continuous. **Primary cell cultures** are obtained from tissue removed from an animal. The tissue is finely minced and then treated with an enzyme, such as trypsin, to disperse individual cells further. The cells are then seeded onto a surface, such as in a flask or a test tube, to form a monolayer. With primary cell lines, only minimal cell division occurs. Cell viability is maintained by periodically removing cells from the surface, diluting them, and placing them into a new container. This process is referred to as *splitting* or *passaging*. Primary cell lines can only be passaged a few times before new cells must be obtained. An example of commonly used primary cell culture is one with primary monkey kidney (PMK) cells.

Finite cell cultures can divide, but passage is limited to about 50 generations. Finite cell lines, like primary cell lines, are **diploid**, that is, they contain two copies of each chromosome. Diploid is the normal genetic makeup for eukaryotic cells. As the number of passages increases, these cells become less sensitive to viral infection. Human neonatal lung is an example of a standard finite cell culture used in diagnostic virology.

Continuous cell cultures are capable of infinite passage and are **heteroploid**, that is, they have an abnormal and variable number of chromosomes. Sometimes the number of chromosomes is not a multiple of the normal haploid number; this is referred to as **aneuploid**. HEP2 (derived from a human laryngeal epidermoid carcinoma), A549 (derived from a human lung carcinoma), and Vero (derived from a monkey kidney) are examples of continuous cell lines used in diagnostic virology. Both HEP2 and A549 were developed from cancer tissue obtained from patients during treatment. Each laboratory must decide which cell lines to use based on the spectrum of viral sensitivity, availability, and cost. Optimally, several different cell lines will be used for a single specimen to recover different viruses that may be present, analogous

to the strategy used with media for the recovery of bacteria. Table 29.3 lists some cell culture lines commonly used in clinical virology.

Mixed or engineered cell cultures are cell lines that contain a mixture of two different cell types or are made up of cells genetically modified to make identification of viral infection easier. Mixed cell lines have been developed by combining two cell lines susceptible to certain types of viruses, such as respiratory or enteric viruses. The mixed line can have greater sensitivity to a wider range of viruses and therefore reduce the number of culture vials that must be incubated. Interpreting these mixed cell cultures is sometimes difficult, but this is well worth the effort when dealing with fastidious viruses.

Cytopathic effect on cell cultures

Some viruses produce a very characteristic CPE that can provide a presumptive identification of a virus isolated from a clinical specimen. For example, HSV grows rapidly on many different cell lines and frequently produces a CPE within 24 hours. A predominantly cell-associated virus, HSV produces a focal CPE (in which adjacent cells become infected) and plaques, or clusters of infected cells. The combination of rapid growth, plaque formation, and growth on many different cell types, such as MRC-5 (Medical Research Council cell strain 5), human fibroblasts, Vero, HEp2, mink lung, and

PMK cells, is presumptive evidence for the identification of HSV. HSV is one of the few viruses that can grow on rabbit kidney cells (Fig. 29.2); therefore it is a useful cell line for HSV detection.

CMV produces an HSV-like CPE (Fig. 29.3) but grows much more slowly and only on diploid fibroblasts. VZV grows on several types of cells, including diploid fibroblasts, A549 cells, and Vero cells. Enteroviruses characteristically produce rather small, round infected cells that spread diffusely on PMK cells, diploid fibroblasts, human embryonal rhabdomyosarcoma (RD) cells, and A549 cells. Adenoviruses also produce cell rounding (Fig. 29.4) on many cell types, including diploid fibroblasts, HEp2 cells, A549 cells, and PMK cells, but this is usually larger than that caused by enteroviruses. The rounding may be diffuse or focal, appearing like a cluster of grapes.

The respiratory viruses may not produce characteristic CPE. RSV can produce classic syncytial formation in HEp2 or MKC cells. **Syncytia** are giant multinucleated cells resulting from cell fusion in response to the RSV infection. PIV type 2, and to a lesser extent PIV type 3, can also produce syncytia. Influenza virus commonly does not exhibit a well-defined CPE. Specimens submitted for influenza virus cultures are usually inoculated onto PMK cells, LLC-MK2 (a continuous line derived from rhesus monkey kidney), or MDCK (Madin-Darby canine kidney epithelial cells) cells. Because influenza

viruses typically do not produce CPE, a hemagglutination or hemadsorption test is done to detect these viruses. Cells infected with influenza virus express viral **hemagglutinin (H)** protein on their surface that binds red blood cells (RBCs). In the hemadsorption test, a suspension of RBCs is added to the infected cell monolayer. If influenza virus is present, the RBCs will adsorb or stick to the infected cells. In the hemagglutination assay, supernatant from the infected monolayer containing influenza virus is mixed with a suspension of RBCs. Influenza viruses also have the H protein on their surface; therefore the RBCs will visibly agglutinate.

Fluorescent antibody stains that detect viral antigen, such as those used directly on clinical specimens, can also be used to screen cell cultures before a final negative result is reported. IF, EIA, and NAATs can also be used to detect and identify viruses in cell cultures to ensure that true positives are not missed.

Centrifugation-enhanced shell vial culture

The shell vial culture technique can more rapidly identify viruses than the traditional cell culture method. Cells are grown on a round coverslip in a shell vial. A shell vial is a small, round, flat-bottomed tube, generally with a screw cap. The shell vial, containing a cell monolayer on the coverslip, is inoculated with the clinical sample and then centrifuged to promote viral absorption. The shell vial is incubated for 24 to 48 hours, after which the coverslip is removed, and an IF assay is performed. Based on the type of clinical specimen

and suspected viruses, a variety of fluorescent-labeled antibodies can be used. A modification of this procedure is to use flat-bottomed microtiter plates. Although this is better than looking for CPE, in many cases it can be labor-intensive, and often cultures are done in duplicate, which results in reading at 24 hours then again at 48 hours, thus increasing the TAT.

Serologic assays to detect antibodies to virus

Viral serology detects circulating antibodies to viruses after exposure. This method provides limited information and has certain inherent problems (see [Chapter 10](#)). First, serologic assays measure the host response rather than directly detecting the virus. Second, the antibody-producing capabilities of human hosts differ widely from person to person. For example, despite being actively infected, immunocompromised individuals may not produce enough antibodies to be detected, and the antibodies produced may be very short-lived. This is typically seen in patients with HIV infection. Third, the antibody level does not necessarily correlate with the acuteness or activity level of the infection because this is also host dependent.

With few exceptions, paired sera (acute and convalescent) demonstrating seroconversion or a fourfold rise in titer are required to establish a diagnosis of recent infection. Therefore serologic studies are usually retrospective. Some assays can distinguish between immunoglobulin M (IgM) and immunoglobulin G (IgG); the presence of IgM indicates an acute (recent) infection. Cross-reactions with nonspecific antibodies can occur, which makes interpretation of results difficult. Interpretation is also difficult because of passive transfer of antibodies, such as in transplacental or transfusion transmission. The following are indications for serologic testing:

- Diagnosis of infections with nonculturable agents, such as hepatitis viruses
- Distinguishing between a past (IgG) or acute (IgM) viral infection
- Determination of immune status regarding rubella virus, measles virus, VZV, hepatitis A virus (HAV), and HBV
- Monitoring of patients who are immunosuppressed or have had transplantations
- Epidemiologic or prevalence studies that are critical during outbreaks to assess overall spreading and herd immunity status

Double-stranded DNA viruses

In this chapter, viruses are discussed in groups based on nucleic acid types: double-stranded DNA (dsDNA), single-stranded DNA (ssDNA), double-stranded RNA (dsRNA), and single-stranded RNA (ssRNA) viruses. Hepatitis viruses are the only exception, and they will be discussed as one group because they do not all have the same type of nucleic acid.

Adenoviridae

Adenovirus was first isolated from adenoid tissue of children and was thus named for the initial isolation location. Human adenoviruses belong to the family Adenoviridae and

Fig. 29.5 Transmission electron micrograph of adenovirus ($\times 60,000$). (Courtesy Dr. G. William Gary, Jr., Centers for Disease Control and Prevention, Atlanta, GA.)

the genus *Mastadenovirus*. Adenoviruses are naked icosahedral viruses with dsDNA (Fig. 29.5). Adenovirus has over 60 distinct serotypes (seven subgenera, A to G), and the different serotypes are associated with numerous common clinical manifestations. The clinical manifestations seen are dependent on the age and immune status of the person infected. Adenovirus is shed in secretions from the eyes and respiratory tract. Viral shedding in feces and urine can occur for days after the symptoms have disappeared. The viruses are spread by aerosols, fomites, the oral-fecal route, and personal contact. Most infections are mild and require no specific treatment. Effective infection control measures, including adequate chlorination of swimming pools, prevent adenovirus infections, such as adenovirus-associated conjunctivitis.

The most common serotypes are 1 to 8, 11, 21, 35, 37, and 40. Although one half of all adenovirus infections are asymptomatic, the virus causes about 10% of all cases of pneumonia and 5% to 15% of all cases of gastroenteritis in children. Adenovirus infections affect the respiratory tract, eye, and gastrointestinal (GI) tract, with lesser involvement of the urinary tract, heart, central nervous system (CNS), liver, pancreas, and genital tract. The viruses can also cause epidemic keratoconjunctivitis, acute hemorrhagic cystitis, and pharyngoconjunctival fever.

Adenovirus infections occur throughout the year and affect every age group. Adenovirus serotype 14 is rarely reported but causes severe and sometimes fatal acute respiratory disease or distress (ARD) in patients of all ages. In the United States, an outbreak of adenovirus 14 was reported in four states from 2006 to 2007. The outbreak included one infant in New York and 140 additional cases from the states of Oregon, Texas, and Washington. Although no link could be found between the New York case and the other cases, all isolates were identical by hexon and fiber gene sequencing. Since 2007, adenovirus has been associated with outbreaks of ARD in U.S. military recruits and the general public. Adenovirus types 3, 4, and 7 are most associated with ARD and can be fatal. A vaccine for types 4 and 7 became available in October 2011 and is used by the U.S. military.

Adenovirus types 40 and 41 are called *enteric adenoviruses* because they cause epidemics of gastroenteritis, usually in young children, with diarrhea being a prominent feature of the

Fig. 29.6 Bronchoalveolar lavage, cytocentrifuge preparation, immunofluorescent antigen adenovirus stain, fluorescence microscopy showing prominent fluorescence of virus-infected cells ($\times 200$).

illness. There is far less vomiting and fever than with rotavirus infections. Enteric adenoviruses have a worldwide, endemic distribution, and the number of cases increases during the warmer months. These adenoviruses can be identified but not serotyped by EIA. Commercial antigen detection kits are available, and although inexpensive, they lack sensitivity. There is a molecular panel (FilmArray, BioFire Diagnostics, Salt Lake City, UT) that is specific for adenovirus types 40 and 41.

Adenoviruses are quite stable and can be isolated in human embryonic kidney and many continuous epithelial cell lines. They produce a characteristic CPE, with swollen cells in grapelike clusters. Isolates can be identified by fluorescent antibody (Fig. 29.6) and EIA methods, along with nucleic acid tests. Serotyping is accomplished by serum neutralization or hemagglutination inhibition. Electron microscopy has been used in several epidemiologic studies, but it is not routinely used as a clinical tool and is mostly only used in research settings.

Herpesviridae

The herpesviruses belong to the family Herpesviridae. The herpesviruses have a genome of linear dsDNA, an icosahedral capsid, an amorphous integument surrounding the capsid, and an outer envelope. All herpesviruses share the property of producing latency and life-long persistence in their hosts. The virus is latent between active infections. It can be activated from latency by various stimuli, including stress, physical exertion, fever, comicrobial infection, hormonal imbalance, and sunlight. Reactivation tends to be milder than the primary infection.

Eight species of human herpesvirus (HHV) are currently known:

- HSV-1, also known as HHV-1
- HSV-2, also known as HHV-2
- VZV, also known as HHV-3
- EBV, also known as HHV-4
- CMV, also known as HHV-5
- HHV-6
- HHV-7
- HHV-8, also known as Kaposi sarcoma (KS) herpesvirus

There are other herpesviruses that infect only primates, except for herpes B virus, which has produced fatal infections in animal handlers and researchers working with primates.

Herpes simplex viruses

HSV-1 and HSV-2 belong to the genus *Simplexvirus*. HSV infections are very common. By adulthood, about 80% of Americans have been infected with HSV-1. Approximately 20% of Americans have had HSV-2 infections. These figures indicate that about one in six persons in the United States has had HSV infection, and most infections are asymptomatic. Disease caused by HSV infection is generally divided into two categories: primary (first or initial infection) and recurrent (reactivation of the latent virus).

Infections are generally spread by contact with contaminated secretions. Lesions usually occur on mucous membranes after an incubation period of 2 to 11 days. Infected individuals are most infectious during the early days of a primary infection. Virus-infected cells are usually found at the edge and in the base of lesions; however, the virus can be transmitted from older lesions as well as from asymptomatic patients.

Types of infections

HSV infections occur worldwide, and infections can cause a wide spectrum of clinical manifestations. HSV-1 and HSV-2 cause the same diseases. Skin vesicles are filled with clear fluid and have a red base. The vesicles progress to pustular lesions, ulcerate, and then finally crust over.

Oral herpes

Most oral herpes infections, *herpes labialis*, are caused by HSV-1, but many cases are caused by HSV-2. The incubation period ranges from 2 days to 2 weeks. Primary infections are usually asymptomatic, but when apparent, they commonly manifest as mucosal fluid-filled vesicles inside the mouth or as ulcerations (gingivostomatitis) that can be widespread and involve the buccal mucosa, posterior pharynx, and gingival and palatal mucosae. In young adults, a primary HSV infection can involve the posterior pharynx and produce acute pharyngitis. Recurrent, or reactivation, HSV infection usually occurs on the border of the lips at the junction of the oral mucosa and skin. An early symptom of burning or pain followed by vesicles, ulcers, and crusted lesions is the typical pattern. These eruptions can result from stress or sunlight exposure and are often quite painful.

Genital herpes

Genital herpes, or *herpes genitalis*, infections are usually caused by HSV-2, although HSV-1 can cause as many as one third of the infections. Many individuals with antibodies to HSV-2 have not been diagnosed with genital herpes. The infection manifests itself in females as vesicles on the mucosa of the labia, vagina, or both. Involvement of the cervix and vulva is not uncommon. In males, the shaft, glans, and prepuce of the penis are the most affected sites. The urethra is commonly involved in both men and women. Recurrent herpes infections involve the same sites as primary infections, but the urethra is less commonly involved. The symptoms are usually less severe in recurrent disease and have a shorter duration. Herpes genitalis can as much as double the risk of sexual transmission of HIV.

Neonatal herpes

Transmission of HSV from infected mothers to neonates is less common than might be expected, but the risk of mother-to-infant transmission is 10 times higher when mothers have an unrecognized primary infection during labor and delivery. Infection can be acquired in utero (during birth) or postnatally (after birth) from hospital personnel or family members. The infection is usually transmitted during a vaginal delivery and is more severe when HSV-2 is involved compared with HSV-1. The rate of transmission is about 50% when the mother has a primary infection. Most newborns are infected by mothers who are asymptotically shedding the virus during a primary infection. The risk of transmission is very low when the mother has recurrent herpes. Cesarean delivery or suppressive antiviral therapy at delivery significantly reduces the risk of transmission. Mortality associated with disseminated neonatal disease is about 60% in treated neonates and exceeds 70% in untreated neonates.

Herpes simplex virus encephalitis

HSV encephalitis is a rare but devastating disease with a mortality rate of about 70%. In the United States, HSV encephalitis may account for up to 20% of all encephalitis cases. HSV is the leading cause of fatal sporadic encephalitis in the United States. Encephalitis is usually caused by HSV-2 in neonates and HSV-1 in older children and adults. HSV encephalitis is also associated with an immunocompromised status. Survival rates and clinical outcomes are greatly improved with IV antiviral treatment.

Ocular herpes

A herpes simplex infection of the conjunctiva can manifest itself as swelling of the eyelids associated with fluid-filled vesicles. Corneal involvement, *herpes keratitis*, can result in destructive ulceration and perforation of the cornea, leading to blindness. HSV is the most common cause of corneal infection in the United States. Fortunately, most infections involve only the superficial epithelial layer and heal completely with treatment.

Diagnosis

Diagnosis of HSV infection is best made by antigen detection or viral isolation in culture. However, smaller laboratories may perform a Tzanck smear from the lesion and look for CPE typical of HSV, and, if present, this can be confirmed using specific fluorescent antibodies to HSV-1 or HSV-2 (Figs. 29.7 and 29.8). Often, other specimen types can also be stained and observed for CPE consistent with HSV infection (Fig. 29.9). However, culture is still considered the gold standard. The best specimens for culture are aspirates from vesicles, open lesions, or host cells collected from infected sites. Culture of CSF is usually not productive. To make a culture-confirmed diagnosis of encephalitis, brain biopsy material is required.

The preferred diagnostic method for HSV in CSF is PCR. In many studies, gene amplification for HSV in CSF approaches 100% sensitivity with almost the same specificity. Some of the newer nucleic acid assays are becoming easier to perform and less costly, so it is expected that they will continue to increase in use in clinical laboratories. A diagnostic panel is available for the detection of HSV-1, HSV-2, and several other viruses and bacteria that cause meningitis (FilmArray, BioFire Diagnostics), and this test is frequently performed to reduce

the need for antiviral therapy, especially in infants. It is rapidly becoming the standard of care for rapid identification of viral encephalitis. There are also several HSV-1/HSV-2 standalone assays that use isothermal amplification, another form of molecular assay that does not need a thermocycler. Diagnosis can be made in a few hours, and appropriate therapy can be initiated quickly, resulting in more favorable patient outcomes.

Fig. 29.10 Advanced cytopathic effect in an A549 cell line caused by herpes simplex virus infection (unstained, $\times 400$). (Courtesy Sarah Pierson.)

In culture, HSV replicates rapidly, and CPE can be seen within 24 hours (Figs. 29.2 and 29.10). Diagnosis in cell cultures is quicker than for many other viruses, but it is not as rapid as molecular assays. HSV can be isolated in numerous cell lines, including human embryonic lung, rabbit kidney, MRC-5, HEp2, and A549 cells. HSV is one of the most frequently isolated viruses in the clinical virology laboratory. Once isolated, monoclonal antibodies can be used to type the virus. Typing genital lesion isolates can be prognostic in that HSV-2 reactivation occurs more readily than HSV-1. In addition, typing genital lesions from children has been used to provide legal evidence supporting potential sexual abuse.

Commercially available engineered cell lines improve the detection of HSV. In the Enzyme Linked Virus Inducible system (ELVIS; BioWhittaker, Walkersville, MD), a gene for the enzyme β -galactosidase linked to a virus-induced promoter has been inserted into baby hamster kidney cells. If HSV-1 is present in the cell line, a viral protein will activate the promoter, resulting in β -galactosidase expression. Detection is accomplished by addition of a chromogenic reagent, which is cleaved by the enzyme produced in virus-infected cells and results in the formation of a blue color, which is easily seen by light microscopy.

Several FDA-approved, type-specific assays that differentiate antibody response to HSV are available. The tests come in a variety of formats, including EIA, strip immunoblot, and even simple membrane-based, point-of-care assays. Newer tests use recombinant or affinity-purified, type-specific glycoprotein G-1 or G-2, giving the tests the ability to distinguish between HSV-1 and HSV-2. Older-generation tests used crude antigen preparations from lysed cell culture of the virus and were shown to have cross-reactivity rates of as much as 82% in positive specimens. With this change, antigen testing has become more specific with much better results in a rapid, low cost, and easy-to-perform assay. However, because of the latent, life-long infections, many adults have antibodies to HSV-1 and HSV-2. Serologic assays can be of value in diagnosing new infections in patients without a history of infection, particularly women who are pregnant.

Cytomegalovirus

CMV is in the genus *Cytomegalovirus*, and the name originates from the enlargement of infected cells (from Latin *cyto*, meaning cell, and *mega*, meaning large). CMV is typically spread by close contact with an infected person. Most adults demonstrate antibodies against the virus, with a prevalence rate in the United States of 55% among adult women and 32% among adult men. The seroprevalence of CMV increases with age in all populations; it is highest among lower socioeconomic groups living in crowded conditions. Persons who live in overcrowded conditions can acquire CMV at an early age. The virus is shed in saliva, tears, urine, stool, and breast milk. CMV infection can also be transmitted sexually via semen and cervical and vaginal secretions and through blood and blood products. CMV infection is the most common congenital infection in the United States.

Most CMV infections are asymptomatic in the immune-competent host but can manifest themselves as a self-limiting, infectious mononucleosis-like illness, with fever and hepatitis. In immunocompromised hosts, such as transplant recipients and patients with HIV infection, CMV infection can become a significant, life-threatening, systemic disease involving almost any organ, including the lungs, liver, intestinal tract, and retina, as well as the CNS.

Congenital infections are often symptomatic and can present with serious clinical manifestations if the mother acquires the primary infection during pregnancy. Congenital infection, however, is unlikely to occur if the mother was seropositive at the time of conception. Symptomatic congenital infection is characterized by petechiae, hepatosplenomegaly, microcephaly, and chorioretinitis. Other manifestations are reduced birth weight, CNS involvement, mental impairment, deafness, and even death. CMV infection is one of the leading causes of deafness and intellectual impairment.

The diagnosis of CMV infection is best confirmed by isolation of the virus from normally sterile body fluids, such as the buffy coat of blood or other internal fluids or tissues. The virus can also be cultured from urine or respiratory secretions, but because shedding of CMV from these sites is common in normal hosts, isolation from these sources must be interpreted with extreme caution. Typically, this is done using standard stains on respiratory specimens looking for inclusions typical of CMV infection (Figs. 29.11 and 29.12).

Fig. 29.11 Bronchoalveolar lavage, centrifuge preparation, rapid Wright-Giemsa stain. Enlarged pneumocyte with intranuclear inclusion. Morphology consistent with cytomegalovirus (CMV). Observe the characteristic nuclear changes for CMV. The cell and nucleus are enlarged, the nucleus is granular, and the nuclear membrane is indistinct (arrow). ($\times 400$).

Fig. 29.12 Bronchoalveolar lavage, centrifuge preparation, rapid Wright-Giemsa stain. Enlarged pneumocyte consistent with cytomegalovirus (CMV). The large regular-sized, magenta cytoplasmic inclusions (arrow), when present, are characteristic of CMV ($\times 400$).

A viral antigenemia test is widely used by clinical virology laboratories. The antigenemia assay is specific, sensitive, rapid, and relatively easy to perform. The test is based on the immunocytochemical detection of the 65-kilodalton (kDa), lower-matrix phosphoprotein (pp65) in the nuclei of infected peripheral WBCs. The antigenemia test is more sensitive and rapid than cell culture, and it can prove helpful in assessing the efficacy of antiviral therapy. However, several newer NAATs may replace this test.

Molecular-based testing is widely used to detect virus particles in clinical samples. PCR, branched DNA, and hybridization assays are all used for diagnostic applications and blood donor screening. Meningitis panels that include CMV are available and are suitable for use in pediatric populations. A congenital infection is best confirmed by isolation of CMV from the infant within the first 2 weeks of life. Isolation after the first 2 weeks does not confirm congenital infection. Urine is the most common specimen submitted for viral detection in these patients. NAATs are the preferred method for determining viral loads.

CMV is a typical herpesvirus, but it replicates only in human cells and more slowly compared with HSV or VZV. CMV can be isolated in cell culture only by using human diploid fibroblast cell lines, such as human embryonic lung or human foreskin fibroblasts (see Fig. 29.3). The virus replicates slowly, so it may take up to 3 weeks for the CPE to appear in culture. However, the use of shell vials can reduce the time for detection to as little as 1 day. CMV produces characteristic CPE, which can sometimes be seen in clinical specimens (Fig. 29.13). Serology is not as helpful as a culture in diagnosing the infection.

Epstein-Barr virus

EBV, in the genus *Lymphocryptovirus*, causes infectious mononucleosis (Fig. 29.14). Up to 95% of adults between 35 and 40 years of age have been infected. Many children become infected with EBV and show few signs of infection. When infection with EBV occurs in adolescence, it presents as infectious mononucleosis 35% to 50% of the time. The signs and symptoms of EBV infection include sore throat, fever, lymphadenopathy, hepatomegaly, splenomegaly, and general malaise. These usually resolve within a few weeks, although

malaise can be prolonged in some cases. Complications of EBV infection include splenic hemorrhage and rupture, hepatitis, thrombocytopenia purpura with hemolytic anemia, Reye syndrome, encephalitis, and other neurologic syndromes. EBV can be recovered from the oropharynx of symptomatic

Fig. 29.13 Active cytomegalovirus lung infection in a patient with acquired immunodeficiency syndrome. Lung histopathology shows cytomegalic pneumocyte containing characteristic intranuclear inclusions (hematoxylin & eosin $\times 1000$). (Courtesy Edwin P. Ewing, Jr., Centers for Disease Control and Prevention, Atlanta, GA.)

Fig. 29.14 Negatively stained transmission electron micrograph revealing the presence of numerous Epstein-Barr virions ($\times 40,000$). (Courtesy Fred Murphy, Centers for Disease Control and Prevention, Atlanta, GA.)

as well as healthy persons, who can transmit the virus to susceptible individuals via infected saliva.

The incubation period for EBV infection ranges from 2 weeks to 2 months. As with the other herpes group viruses, infection is very common and results in latency, and most adults demonstrate antibodies against the virus. Young children with the infection are almost always asymptomatic. As the age at the time of infection increases to young adulthood, a corresponding increase occurs in the ratio of symptomatic to asymptomatic infections.

Some cancers have been associated with EBV, including Burkitt lymphoma, Hodgkin disease, and nasopharyngeal carcinoma (NPC). Burkitt lymphoma is a malignant disease of the lymphoid tissue seen most commonly in African children. The virus has also been increasingly recognized as an important infectious agent in transplant recipients. The most significant clinical effect of EBV infection in these patients is the development of a B-cell lymphoproliferative disorder or lymphoma.

Viral culture for EBV requires human B lymphocytes and is beyond the capabilities of most clinical virology laboratories. Therefore laboratory diagnosis of EBV infection is often accomplished with serologic tests. EBV infects circulating B lymphocytes and stimulates them to produce multiple heterophile antibodies, including antibodies to sheep and horse RBCs. The Paul-Bunnell heterophile antibody test is an excellent rapid screening test for these antibodies, although some false-positive reactions do occur. Many rapid test kits, generally based on EIA or latex agglutination, are commercially available for detecting heterophile antibodies. These tests are 80% to 85% effective. Some false-positive test results represent patients who have had an EBV infection and still have low antibody levels. Young children can have false-negative results with the heterophile test; performing an EBV-specific antibody test on these individuals is appropriate. EBV-specific serologic tests (Table 29.4; Fig. 29.15) include the following:

- *Anti-VCA (antibodies to the viral capsid antigen)*: IgM to the VCA occurs early in the infection and disappears in about 4 weeks, so its presence indicates current infection. IgG often appears in the acute stage and will persist for life at lower titers.
- *Anti-EA IgG (IgG antibody to early antigen)*: IgG to EA can appear in the acute phase, and its presence indicates current or recent infection. The antibody usually cannot be detected after 6 months.
- *Anti-EA/D (antibody to early antigen, diffuse)*: Antibodies to EA/D appear in the acute phase, and their presence indicates current or recent infection. The antibodies

Table 29.4 Interpretation of Epstein-Barr virus serologic markers

PB	Anti-VCA IgM	Anti-VCA IgG	Anti-EA IgG	Anti-EBNA	Interpretation

+	+	+	±	—	Acute infectious mononucleosis
±	±	+	±	+	Recent infection
—	—	+	—	+	Past infection

—, Negative; +, positive; ± positive or negative; *Anti-EA IgG*, immunoglobulin G antibodies to early antigen; *anti-EBNA*, antibodies to Epstein-Barr virus nuclear antigen; *anti-VCA IgG*, immunoglobulin G antibodies against the viral capsid antigen; *anti-VCA IgM*, immunoglobulin M antibodies against the viral capsid antigen; *PB*, Paul-Bunnell antibody.

Fig. 29.15 Serologic evaluation of Epstein-Barr virus infection (infectious mononucleosis) showing the increase and decrease of detectable antibodies. *Anti-EA*, Antibody to early antigen; *anti-EBNA*, antibody to Epstein-Barr virus nuclear antigen; *anti-VCA IgG*, immunoglobulin G antibody to the viral capsid antigen; *anti-VCA IgM*, immunoglobulin M antibody to the viral capsid antigen; *PB*, Paul-Bunnell heterophile antibody.

usually cannot be detected after 6 months. Patients with NPC often have elevated levels of IgG and IgA anti-EA/D antibodies.

- *Anti-EA/R (antibody to early antigen, restricted)*: Antibodies to EA/R appear in the acute phase and disappear soon after anti-EA/D, but they can persist for up to 2 years and may be life-long in some patients. The anti-EA/R IgG antibody level is elevated in patients with Burkitt lymphoma.
- *Anti-EBNA (antibody to the EBV nuclear antigen)*: Antibodies appear about 1 month after infection, with titers peaking in 6 to 12 months.

Several molecular assays that use real-time PCR to detect and quantitate viral load are coming to market and will be key to evaluating treatment effectiveness for patients who are EBV-positive. This will especially be critical in patients who have other medical conditions that lower immune response, such as HIV infection, diabetes, or cancer.

Varicella-zoster virus

VZV is in the genus *Varicellovirus*. VZV spreads by droplet inhalation or direct contact with infectious lesions. Cell-free virus is produced at very high levels in the skin vesicles, thus the fluid from these vesicles is highly infectious. The virus causes two different clinical manifestations: varicella (chickenpox) and zoster (shingles). In the United States, more than 90% of adults have antibodies to VZV. Varicella is the primary infection and is highly contagious (Fig. 29.16). In contrast with infections caused by other herpesviruses that do not usually manifest symptoms, varicella is generally clinically apparent. It commonly appears in childhood and includes symptoms such as a mild febrile illness, rash, and vesicular lesions. Usually, the lesions appear first on the head and trunk and then spread to the limbs. The lesions dry, crust over, and heal in 1 to 2 weeks. Painful oral mucosal lesions may develop, particularly in adults.

Herpes zoster, or shingles, is the clinical manifestation caused by reactivation of VZV; it usually occurs in adults. Approximately one in three adults will develop herpes zoster in their lifetime. It is thought that the virus remains latent in the dorsal root or cranial nerve ganglia after primary

Fig. 29.16 Electron micrograph of a varicella virus ($\times 100,000$). (Courtesy Erskine Palmer and B.G. Partin, Centers for Disease Control and Prevention, Atlanta, GA.)

infection. In a small proportion of patients, the virus becomes reactivated, travels down the nerve, and causes zoster. The most common presentation is rash, followed by vesicular lesions in a unilateral dermatome pattern. These lesions may be associated with prolonged disabling pain that can remain for months, long after the vesicular lesions disappear.

VZV infection is usually diagnosed based on characteristic clinical findings. Some smaller laboratories use smears made with standard stains from lesion specimens to detect cellular inclusions typical of VZV (Fig. 29.17). In atypical cases, such as in immunocompromised patients, the diagnosis may be more difficult or questionable. In such patients, culture of fresh lesions (vesicles) or the use of fluorescent-labeled monoclonal antibodies against VZV confirms the diagnosis. VZV can be cultured on human embryonic lung or Vero cells. Cytopathic changes may not be evident for 3 to 7 days.

Recently, NAATs, such as PCR assays, have become the standard for the diagnosis of VZV disease. These assays have

Fig. 29.17 Skin vesicle fluid, Tzanck preparation, Wright-Giemsa stain. Multinucleated epithelial cells present. Intranuclear inclusions present. Morphology consistent with herpes viral inclusions, varicella-zoster virus infection ($\times 400$).

revolutionized the diagnosis of VZV disease of the CNS and of disseminated VZV infection, especially in immunocompromised patients (e.g., HIV infection, diabetes), and the identification of herpes zoster in patients who do not develop the rash associated with VZV. The advantages of these molecular assays are that they require small specimen volumes and are highly sensitive, specific, and rapid.

An attenuated vaccine to prevent chickenpox was approved for use in the United States in 1995. Before routine use of the vaccine in children, an estimated 4 million to 5 million cases occurred annually. The vaccine is expected to give life-long immunity. In 2006, a single-dose, attenuated VZV vaccine for shingles, Zostavax (Merck, Whitehouse Station, NJ), was approved. In 2017, Shingrix (GlaxoSmithKline, Philadelphia, PA), a recombinant subunit adjuvanted vaccine, was approved; this is a two-dose vaccine. It is currently the only FDA-approved vaccine available to prevent shingles. The shingles vaccine is recommended for individuals 50 years of age and older. Antiviral treatment of VZV infection and reactivation is possible and is quite effective in reducing the infection time for patients, especially if coupled with more rapid molecular diagnostics.

Human herpesvirus 6

HHV-6 is in the genus *Roseolovirus*. The two variants of the virus, A and B, are indistinguishable serologically, but variant B appears to be the cause of disease. HHV-6 is a common pathogen. About 95% of young adults are seropositive. Studies have shown that the virus persists in the salivary glands and has been isolated from stool specimens, but most evidence indicates that saliva is the most likely route of transmission. Inhalation of respiratory droplets from and close contact with infected individuals is the primary portal of entry.

HHV-6 has been associated with the childhood disease *roseola*, which is also called *roseola infantum*, *exanthem subitum*, and *sixth disease*, reflecting its role as the sixth childhood rash. Children are protected by maternal antibodies until approximately 6 months of age. Seroconversion occurs in 90% of children between 6 months and 2 years of age. In immunocompetent individuals, most infections are mild or asymptomatic. When symptoms occur, the disease is acute and febrile; a maculopapular rash appears as the fever resolves. About 30% to 40% of infected children with symptoms experience seizures. As with all members of the family Herpesviridae, reactivation

of latent infections can become clinically significant in immunocompromised individuals. HHV-6 has also been proposed as having some involvement in the development of progressive multifocal leukoencephalopathy and multiple sclerosis.

The diagnosis of HHV-6 infection is usually made clinically. Isolation of the virus is most sensitive with lymphocyte cell culture, which is not practical for routine diagnosis. Serology may not be helpful unless paired sera are available. Patients do not usually have a positive IgM result until about 5 days after infection; IgG appears several days later. PCR and viral load testing offer the most sensitive and specific means of diagnosing primary HHV-6 infection.

Human herpesvirus 7

HHV-7 is in the genus *Roseolovirus* with HHV-6. The CD4 molecule serves as a receptor for HHV-7 to infect T lymphocytes. It also uses other receptors and has a broad range of host cells. Like HHV-6, HHV-7 is extremely common and is shed in the saliva of 75% of adults. The virus causes roseola, which is clinically identical to that caused by HHV-6. HHV-7 causes latent infections in T lymphocytes. Despite the similarities between HHV-6 and HHV-7, their antigenic diversity is such that antibodies to one virus do not protect against infection from the other. In addition, exposure to HHV-7 seems to occur later in life than exposure to HHV-6. Most 2-year-olds are seronegative for HHV-7, but most children are seropositive by 6 years of age.

HHV-7 can be isolated in culture in peripheral blood lymphocytes or in cord blood lymphocytes. Although the virus can be isolated from the saliva of healthy individuals, it is rarely isolated from peripheral blood mononuclear cells. PCR assay can detect the virus, but the ubiquitous nature of the virus can lead to difficulties in interpreting the results. Serologic results can be confusing because of cross-reactions, but patients with increasing levels of antibody to HHV-7 but not to HHV-6 may have an active HHV-7 infection.

Human herpesvirus 8

HHV-8, in the genus *Rhadinovirus*, can be detected in all forms of KS, including acquired immunodeficiency syndrome (AIDS)-related, Mediterranean, and HIV-1-negative KS, which is endemic to Africa, as well as posttransplantation KS. This association has earned it as the more common name *Kaposi sarcoma-associated herpesvirus*. It has also been shown to play a role in the development of primary effusion lymphomas and multicentric Castleman disease.

In North America and much of Europe, HHV-8 appears to be transmitted primarily through sexual contact, but studies in Africa and some Mediterranean populations suggest transmission by more casual means. The pattern of infection is like that of HSV-2, although men who have sex with men (MSM) seem to be more susceptible than heterosexuals. Prevalence ranges from close to zero in a study of Japanese blood donors to more than 50% in some parts of Africa. In HIV-positive persons, the seroprevalence can be as much as 20% to 50% higher than that of the surrounding healthy population. In the United States, as many as 20% of normal adults have antibodies to HHV-8, as do 27% of patients with HIV-1 who do not have KS and 60% of patients with HIV and KS.

Currently, the virus cannot be recovered in cell culture. PCR assay, although considered very sensitive, was shown

to be less sensitive than some immunologic assays. However, PCR assay has been used to detect the virus in various specimens, including tissue, blood, bone marrow, saliva, and semen. HHV-8 DNA or antigens are rarely detected in immunocompetent individuals, even if they are seropositive. In situ hybridization can detect HHV-8-affected tissue. The availability of commercially prepared monoclonal antibodies has made the identification of HHV-8-infected cells in various types of lesions by immunohistochemistry more common. Serologic tests are being evaluated and may soon be available.

Papillomaviridae

HPVs, the cause of papillomas (or warts), are clustered in five genera (see Table 29.1). Most clinically significant HPVs are found in the genus *Alphapapillomavirus*, which includes types infecting the genital and nongenital mucosa and genital cutaneous surfaces as well as types most often seen in human cancers. Although associated with the common wart, some HPV types are linked to cancers, including cervical cancer. There are more than 100 types of these small dsDNA viruses; more than 40 types are sexually transmitted and are known as the genital types. HPV 1, 2, 3, and 4 are thought to infect all children and young adults universally, with no significant consequences. Different HPV types exhibit different tissue tropism based on the type of epithelial cells that the viruses preferentially infect: cutaneous or mucosal. The genital HPVs are further categorized as low, intermediate, or high risk based on their association with genital tract cancers. Table 29.5 lists some HPV types and their clinical significance.

Cervical HPV lesions typically consist of flat areas of dysplasia and are often difficult to see. Rinsing the area with 5% acetic acid, which turns the lesion white, makes the lesions more visible; however, due to low sensitivity this method is not used for diagnosis. Some types of HPV will result in genital wart formation (condylomata acuminata) that can easily

be identified. Lesions can be removed by several methods, including surgery, cryotherapy, and laser.

The HPVs cannot be grown in cell cultures; therefore laboratory diagnosis of HPV infection often involves cytology sections. Cytotechnologists and cytopathologists examine Pap smears looking for koilocytes, cells with perinuclear clearing accompanied by an increased density of the surrounding rim of cytoplasm, which are indicative of HPV infection. Additional testing, such as nucleic acid probe tests, can help detect HPV DNA in endocervical cells and identify the HPV type. PCR techniques are more sensitive and have shown that HPV is present in 95% or more of invasive cervical cancers, but the presence of the virus alone is not the sole factor in cancer development. As many as one third of all college-age women are infected with HPV, and most develop only subclinical infections. Because finding HPV in cervical tissue is not the sole predictor of invasive disease, there is some debate about whether it is useful to look routinely for the virus in cervical specimens.

A quadrivalent vaccine, Gardasil (Merck, Kenilworth, NJ), against HPV types 6, 11, 16, and 18 to prevent cervical cancer was approved by the FDA in 2006 for females 9 to 26 years of age; the vaccine was approved for use in males in 2009. A second vaccine that protects against HPV types 16 and 18, Cervarix (GlaxoSmithKline), was approved for use in women in 2009. HPV types 16 and 18 are linked to most cervical cancers and other HPV-associated cancers. There has been controversy about the use of these vaccines because it is recommended that they be administered at a young age, preferably before sexual activity.

Poxviridae

Poxviruses belong to the family Poxviridae, and they are among the largest of all viruses. They are about 225 to 450 nm long and about 140 to 260 nm wide. These viruses have a characteristic brick shape and contain a dsDNA genome. Variola

Table 29.5 Human papillomaviruses and their clinical significance		
Human papillomavirus type	Clinical manifestation	Association with malignancy
Cutaneous		
1	Plantar warts	None
2–4	Common warts	None
5, 8, 9, 12, 14, 15, 17, 19–25, 36–38	Flat and macular warts	>30% of patients with epidermodysplasia verruciformis (a rare autosomal disease) with types 5, 8, 14, 17, and 20 develop malignancy
26–29, 34	Common and flat warts	Frequent, especially in immunocompromised patients
Mucosal		
6, 11	Papillomatosis, primarily laryngeal, also upper respiratory tract and condylomata acuminata (genital warts)	Low risk
42, 43, 44	Condylomata acuminata	Low risk
31, 33, 35, 51, 52	Condylomata acuminata	Intermediate risk
16, 18, 45, 56, 58, 59, 68	Condylomata acuminata	High risk
Modified from Gravitt, P. E., & Ginocchio, C. C. (2011). Human papillomaviruses. In J. Versalovic, et al. (Eds), <i>Manual of clinical microbiology</i> (10th ed., p. 1612). Washington, DC: ASM Press; 2011.		

virus belongs to the genus *Orthopoxvirus*. Members of the genus include **vaccinia virus** (the smallpox vaccine strain), monkeypox virus, cowpox virus, among others.

Variola virus

Variola virus causes smallpox, a disease that was common throughout early history (Fig. 29.18). Edward Jenner demonstrated the efficacy of vaccination against smallpox in 1796, which ultimately led to control and eradication of the disease. The last reported case of smallpox in the United States was in 1949, and the last case of smallpox worldwide was in Somalia in 1977. After decades of aggressive efforts toward vaccination, education, and eradication, the WHO officially declared the world smallpox free in May 1980. Although extinct in nature, smallpox virus is known to be maintained in at least two locations: in the United States at the Centers for Disease Control and Prevention (CDC) and in Russia. These viruses are maintained under strict security measures, and their very existence remains a point of contention between scientists who advocate their destruction and those who wish to continue studying the virus. The two countries continue to defend maintaining these stocks on the grounds that further study is needed to produce better vaccines and as countermeasures to bioterrorism.

Typically, smallpox is characterized as a synchronous progressive rash accompanied by fever. The incubation period is approximately 10 to 17 days. The patient becomes febrile, and oral lesions can appear. At this point, the patient is infectious. Within 24 to 48 hours, a faint macular rash develops on all parts of the body. However, lesions are present in greater concentration on the head and limbs (centrifugal distribution), including the palms and soles. The macular rash progresses into papules, then vesicles, and finally into pustules that resemble chickenpox lesions. Pustules are deeply embedded into tissues. All lesions change at the same time—hence the term *synchronous*. Infected persons with dark skin tones typically scar as a result of this infection because of the depth of the pustules. The mortality rate for smallpox was, on average, 30%. Other forms of smallpox, including flat and hemorrhagic smallpox, occurred rarely and were almost always fatal.

Fig. 29.18 Negatively stained transmission electron micrograph of the smallpox (variola) virus ($\times 100,000$). (Courtesy J. Nakano, Centers for Disease Control and Prevention, Atlanta, GA.)

Routine vaccination against smallpox in the United States ended in 1972, and other countries have also stopped their vaccination programs. Two vaccines are approved for use in the United States: ACAM2000, manufactured by Sanofi Pasteur Biologics (Canton, MA), and JYNNEOS, produced by Bavarian Nordic (Denmark). Although smallpox was eradicated with the use of a relatively safe vaccine, most of today's population is now susceptible to infection because vaccination is thought to offer protection for only up to 10 years. Because most humans are now susceptible to variola virus, it remains a threat as a bioterrorism weapon. Most military personnel moving into areas of conflict receive the vaccine, with little to no ill effects. If an outbreak of smallpox were to occur, there is sufficient stock of smallpox vaccine to mount an effective vaccination program in the United States. The antiviral compounds cidofovir and brincidofovir have been shown to be effective in combating disease in humans. More information on smallpox as an agent of bioterrorism can be found in [Chapter 30](#).

Monkeypox virus

Monkeypox was first described in primates in 1958, with the first case of human monkeypox in 1970. In 2003, a multistate outbreak of monkeypox occurred in the United States. It is thought that the virus was introduced into the country by rodents imported from Africa (Gambian rats). Human monkeypox infection occurs primarily in central and western Africa. Human infections are rare but result in a vesicular, pustular febrile illness that is very similar to smallpox. Monkeypox infections are less severe in humans compared with smallpox, and mortality rates are significantly lower.

In 2022, an outbreak of monkeypox occurred in 75 countries. The WHO reported 18,095 laboratory confirmed and suspected cases and 5 deaths between January 1 and July 22, 2022. The majority of the cases (72%) were reported in the European region, although the United States reported more cases than any other country. In July, the WHO declared monkeypox a global emergency. It has been suggested that monkeypox virus might have been circulating below detectable levels and maintained undetected human-to-human transmission for a period of time. It is unknown how people in this outbreak were exposed. Data suggest it is transmitted by close personal contact, and a number of cases have been found in gay, bisexual, and other men who have sex with men.

Vaccination for smallpox provides some degree of protection against monkeypox virus. There has been a concerning rise in the number of cases of monkeypox infection in non-endemic countries in recent years, indicating a weakening of protective immunity or emergence of mutant strains that are not protected by the smallpox vaccination.

Single-stranded DNA viruses

Parvoviridae

The smallest of the DNA viruses are the family Parvoviridae, which are naked ssDNA viruses that measure about 22 to 26 nm in diameter. Parvovirus B19 is the principal human pathogen in the family. It is classified in the genus *Erythrovirus*. Parvovirus B19 was named after the serum sample (number 19 of panel B)

in which the initial viral isolate was observed by electron microscopy.

Infections range from asymptomatic to potentially fatal. The most recognized syndrome is erythema infectiosum, more commonly referred to as *fifth disease*. Patients with erythema infectiosum experience a prodrome of fever, headache, malaise, and myalgia, with respiratory and GI symptoms (nausea and vomiting). The prodromal phase lasts a few days, after which a rash often appears. The rash gives a slapped cheek appearance and then spreads to the trunk and limbs. The rash occurs more commonly in children than in adults, lasts up to 2 weeks, and can recur after exposure to heat and sunlight. Adults may also experience arthralgia, arthritis, or both. In some cases, the connective tissue manifestation occurs without the prodrome or rash stage. Most infections occur in children and adolescents, and 80% of adults are seropositive by 65 years of age.

Parvovirus B19 viremia can cause transient aplastic crisis, a self-limiting erythropoietic arrest. Erythroid precursor cells contain a receptor for the virus, allowing viral infection and replication. The disease is characterized by a decrease in RBC production in bone marrow. In otherwise normal individuals, this decrease results in a short-lived anemia. The disease can be severe; complications include viremia, thrombocytopenia, granulocytopenia, pancytopenia, flulike symptoms, and congestive heart failure. Within about 1 week, reticulocytosis occurs, and the patient recovers. Persons with weakened immune systems caused by HIV infection, organ transplantation, cancer, or leukemia are at risk for serious complications from fifth disease.

Parvovirus B19 viremia creates a risk for fetuses and blood transmission in blood units. In utero infection can cause hydrops fetalis resulting from anemia. Although the most vulnerable period for the fetus is the third trimester, most women exposed to the virus do not develop an acute disease, and few infections result in loss of the fetus. The infection usually does not require therapy other than relief of symptoms, such as anti-inflammatory agents for painful joints and generalized aches.

A novel parvovirus was described in 2005. It was named the *human bocavirus* (HBoV) and causes a variety of upper and lower respiratory tract illnesses. Other viruses related to the first HBoV isolate, namely HBoV2, HBoV3, and HBoV4, have been detected principally in human feces. All of these viruses have been found in patients with gastroenteritis and in healthy controls, with HBoV2 found most often. HBoV is closely related to the bovine parvovirus and canine minute virus, both members of the genus *Bocavirus* in the family Parvoviridae. Clinical symptoms of HBoV infection include cough, rhinorrhea, fever, difficulty breathing, diarrhea, conjunctivitis, and rash. HBoV has been increasingly present as a co-infection with RSV and human metapneumovirus (HMPV). Some studies have indicated a potential link to HBoV respiratory illness and gastroenteritis. However, researchers concluded that HBoV is shed in high quantities in stool, but its link to gastroenteritis has not been demonstrated.

HBoV infection is highest during the winter months and has been detected worldwide in 5% to 10% of children 7 to 18 months of age with upper and lower respiratory tract infections. Since its first description, HBoV has been described in at least 19 countries on 5 continents. HBoV was detected less frequently than common respiratory agents (e.g., influenza virus, parainfluenza virus, adenovirus, RSV) in South African

children. Detection of HBoV has improved with the development of sensitive and specific RT-PCR assays.

Double-stranded RNA viruses

Reoviridae

Rotaviruses

Rotaviruses are naked viruses about 75 nm in diameter, with two protein layers surrounding the capsid. They belong to the genus *Rotavirus*. Rotaviruses are the most common cause of viral gastroenteritis in infants and children. Gastroenteritis is a major cause of infant death and failure to thrive. Rotaviruses have a worldwide distribution and in 2016 caused an estimated 258 million cases of diarrhea and 128,500 deaths in children less than 5 years of age. Death rates have declined due to increased availability of a vaccine. However, rotavirus accounted for 29% of all diarrhea deaths in children younger than 5 years of age. Most outbreaks occur in the winter months in the temperate zones and year-round in subtropical and tropical regions.

Rotaviruses are spread by the fecal-oral route and have an incubation period of 1 to 4 days. Symptoms generally occur suddenly and include vomiting, diarrhea, fever, and in many cases, abdominal pain and respiratory symptoms. Vomiting and diarrhea can cause rapid loss of fluids and fatal dehydration. The rotavirus replicates in the epithelial cells in the tips of the microvilli of the small intestine. The microvilli are stunted, and adsorption is reduced. The virus is shed in large quantities in the stool and can cause healthcare-associated outbreaks in the absence of good hygiene. Although the rotavirus is present in large numbers in feces, it can be isolated only with special procedures. Enzyme-linked immunosorbent assay (ELISA) and latex agglutination tests detect the viral antigens in fecal material. Rapid membrane-bound colorimetric tests are also available. Electron microscopy examination of stool samples can be used; however, as mentioned previously, this method is not very sensitive.

With the introduction in 2006 of a human-bovine rotavirus vaccine, RotaTeq (RV5; Merck), a delay in the onset of rotavirus season was seen from mid-November to late February. RotaTeq protects against five strains of RSV and is a series of three oral vaccines administered beginning at age 6 to 12 weeks. A second vaccine, Rotarix (RV1; GlaxoSmithKline), was approved in June 2008. In clinical trials, both vaccines were shown to be safe and effective. During approximately the first year of an infant's life, the rotavirus vaccine prevented 85% to 98% of severe rotavirus illness episodes and prevented 74% to 87% of all rotavirus illness episodes, which was a significant reduction in both populations.

Colorado tick fever virus

The genus *Coltivirus* contains the Colorado tick fever virus that causes a dengue-like infection in the western United States and Canada. It is an 80-nm spherical particle with two outer shells containing 12 RNA segments. Because Colorado tick fever is not reportable, actual numbers of cases are unknown. It is thought to be one of the most common diseases transmitted by ticks in the United States. Viruses transmitted by arthropods, such as ticks and mosquitoes,

are referred to as **arboviruses**. The vector for the infection is *Dermacentor andersoni*, which has many hosts in nature, including deer, squirrels, and rabbits. Infected individuals develop fever, photophobia, myalgia, arthralgia, and chills. As with dengue fever, patients can also have a biphasic fever with a rash, and children can experience hemorrhagic fever. No commercially produced laboratory tests are available, but recombinant immunoassays to detect Colorado tick fever IgG have been developed. Some nucleic acid-based assays using RT-PCR in research laboratories are becoming available and may be helpful in the future. Many primary health care providers rely on ruling out other tickborne diseases to diagnose Colorado tick fever.

Single-stranded RNA viruses

Arenaviridae

The arenaviruses get their name from the Latin *arena*, meaning “sand.” Under an electron microscope, arenaviruses appear sandy and granular. There are 43 named arenaviruses; the family includes many species that cause hemorrhagic fever. Arenaviruses are commonly divided into two complexes: Old World and New World. The New World complex includes the common human pathogens Tacaribe, Junín, and Machupo viruses, among several others. The Old World complex contains the arenaviruses commonly associated with human infection, the lymphocytic choriomeningitis (LCM) virus and the Lassa viruses, and also the benign Lassa-like Mopeia, Mobala, and Ippy viruses. Recently, a new arenavirus was identified from humans, the Lujo virus, during an outbreak of human fatal hemorrhagic fever, in which person-to-person transmission was documented. Some of the arenaviruses have not yet been isolated and are known only from molecular sequencing data.

The first arenavirus to be described was LCM virus in 1933. The first arenavirus found to cause hemorrhagic fever was Junín virus, which causes Argentine hemorrhagic fever. In 1969, Lassa virus was isolated in Africa, and it became the basis of the novel *Fever* by John Fuller. The book details the emergence of Lassa fever, which in retrospect is eerily like the emergence of other hemorrhagic fevers, including Ebola virus (EBOV) disease, which would be identified later in Africa.

The arenaviruses infect rodents, and humans are exposed to the disease by zoonotic transmission. All have been isolated from rodents of the family Muridae. The rodents are infected for long periods and typically do not become ill, but they shed virus in urine, feces, and saliva. In some parts of the United States, as many as 20% of *Mus musculus* mice carry LCM virus. Pet hamsters are also reservoirs. Humans become infected when they inhale the aerosolized virus or contact fomites. LCM virus causes flulike illness; about 25% of infected individuals develop meningitis.

Lassa virus is the most well-known of the arenaviruses. Most exposed individuals develop an asymptomatic infection, but some patients experience fever, headache, pharyngitis, myalgia, diarrhea, and vomiting. Some patients develop pleural effusions, hypotension, and hemorrhaging. CNS involvement includes seizures and encephalopathy. The mortality rate is about 15% for patients needing hospitalization. West African nations are most affected, with more

than 200,000 cases and approximately 3000 deaths occurring annually.

Spread of the virus through airline travel by people from endemic areas highlights the vulnerability of large populations; this combined with the resurgence of the infection in Nigeria has prompted vaccine development efforts. Most cases of Lassa fever are community acquired, primarily through contact with excretions from the multimammate rat *Mastomys natalensis*, which, once infected, sheds the virus throughout its life. Humans inhale the aerosolized virus or contract the virus directly through breaks in skin. Lassa virus is present in throat secretions, can be transmitted from person to person, and can also be transmitted through sexual contact and nosocomially. If therapy begins within the first 6 days of exposure, Lassa virus infection can be effectively treated with the antiviral drug ribavirin. Diagnosis of Lassa virus infection is typically made with ELISA to detect IgM and IgG antibodies.

Bunyavirales

The order Bunyavirales includes the families Peribunyaviridae (genus *Orthobunyavirus*), Nairoviridae (genus *Orthonairovirus*), and Phenuiviridae (*Phlebovirus*), all of which are classified as arboviruses. These viruses replicate initially in the gut of the arthropod vector and eventually appear in saliva. The arthropod transmits the virus when feeding on the blood of vertebrate hosts, including humans. After a few days, the infected host usually develops an asymptomatic viremia; however, some hosts become febrile, which is far less common. Most members of the order Bunyavirales cause a febrile illness, hemorrhagic fever, or encephalitis. Rift Valley fever virus targets the brain and liver to cause encephalitis and hepatitis. La Crosse virus (LACV) and California encephalitis virus cause encephalitis, and Crimean-Congo hemorrhagic fever (CCHF) virus infects the vascular endothelium and liver. The hantaviruses, which belong to the family *Hantaviridae* (genus *Orthohantavirus*) within the order Bunyavirales, do not infect arthropod hosts. They are rodent-borne viruses. Hantaviruses typically affect the peritoneal cavity, thoracic cavity, kidneys, or lungs.

The CCHF virus causes a high-mortality infection in humans. Infection begins with fever, myalgia, arthralgia, and photophobia. Patients exhibit mental status changes, ranging from confusion and agitation to depression and drowsiness. Petechiae and ecchymoses can form on mucosal surfaces and the skin. The patient may bleed from the bowel, nose, and gums. About 30% of patients die. Others begin recovering after about 10 days of illness. Healthcare-associated transmission of CCHF virus has been reported.

In the United States, LACV is a reportable disease. About 50 to 150 severe CNS diseases are reported annually. The incidence is underestimated because the disease manifests as a nonspecific fever, headache, nausea, vomiting, and lethargy. The disease is commonly found in children and usually develops in the summer, frequently referred to as the *summer flu* or *summer cold*. Because serologic tests for LACV are not offered in most laboratories and because this disease has very low mortality (about 1%), a definitive diagnosis is not often made.

The genus *Orthohantavirus* includes Hantaan virus, Seoul virus, Puumala virus, and Dobrava virus, which cause the disease *hemorrhagic fever with renal syndrome* (HFRS). These viruses are present in Asia and Europe, except for Seoul virus,

which is found worldwide. Hantaviruses endemic to Europe and Asia are called *Old World hantaviruses*. Puumala virus is the most common member of this genus in Europe and causes a mild form of HFRS, called *nephropathia epidemica*. Viruses causing HFRS target the kidneys. Patients develop a febrile prodrome and enter a phase of fever and shock, accompanied by oliguria. As the patient recovers, the kidneys gradually regain function. The mortality rate for HFRS is 1% to 15%.

In 1993, two adults from the same household in New Mexico died of an unusual respiratory illness. Serologic testing indicated that these patients had been exposed to an unknown agent that was antigenically related to one of the Asian hantaviruses despite the different clinical presentation. Serology surveys also determined that 30% of the deer mice tested in the New Mexico area were seropositive for the same unknown virus. The virus was ultimately characterized as a new hantavirus and was named the *Sin Nombre* (“without a name”) virus (SNV). The disease caused by this virus was named *hantavirus pulmonary syndrome* (HPS). Molecular techniques were subsequently developed to detect many new hantaviruses in the Americas (Table 29.6), sometimes called the *New World hantaviruses*.

SNV is transmitted through inhalation of contaminated aerosolized mouse urine, saliva, and feces. Generally, person-to-person transmission does not occur with hantavirus. Patients with HPS have a 3- to 5-day febrile prodrome, with fever, chills, and myalgia. Patients then enter a phase of hypotensive shock and pulmonary edema. The patient develops tachycardia, hypoxia, and hypotension. In severe cases, the patient can develop disseminated intravascular coagulation. The mortality rate for HPS is about 50%. Treatment for HPS is primarily supportive. No FDA-approved laboratory tests for the identification of a hantavirus infection are available; however, some European tests are being evaluated. Some

state health laboratories and the CDC perform EIAs to detect anti-SNV IgM and IgG antibodies, which may provide some useful information on the infection. Immunohistochemistry is a sensitive method used to detect hantavirus antigens in the capillary endothelium; a high concentration of antigens is found in capillary tissue specimens from the lung.

Caliciviridae

The family Caliciviridae contains 10 genera; *Norovirus* and *Sapovirus* are the most clinically significant. NoVs (Fig. 29.19) are the most common cause of infectious gastroenteritis in the United States, accounting for as many as 19 to 21 million cases annually and 900 deaths. Most deaths occur in adults 65 years of age and older. Until recently, these small, round ssRNA viruses, 27 to 30 nm in diameter, were called *Norwalk-like viruses*, *caliciviruses*, and *small round structured viruses*. They are currently placed in the genus *Norovirus*. They cause outbreaks of acute gastroenteritis in schools, colleges, nursing homes, and families as well as on cruise ships and in resort areas. NoVs have been found in drinking water, swimming areas, and contaminated food. Transmission is most commonly foodborne, although waterborne and person-to-person transmission can be significant.

The incubation period is 24 to 48 hours; the onset of severe nausea, vomiting, diarrhea, and low-grade fever is abrupt. The infection rate can be as high as 50%. The illness usually subsides within 72 hours. Immunity may be short-lived, leading to the potential for multiple infections throughout life.

The viruses cannot be grown in culture, so diagnosis relies on electron microscopy, immune electron microscopy, and real-time PCR. RT-PCR is now the most used diagnostic assay for detecting NoV. This assay detects viral RNA and can be used to test stool, vomitus, and environmental samples. Stool is the best sample to use to detect NoV. It should be collected when a person has acute illness, within 48 to 72 hours after onset of symptoms. In some cases, NoV can be detected in stool samples collected 2 weeks after recovery. Several EIAs for detecting NoV in stool samples are available. The FDA has approved an EIA for detecting NoV during outbreaks. However, at this time, EIAs are not sensitive enough for diagnosing individuals suspected of being infected.

Sapporo viruses are small (30–35 nm in diameter) diarrheagenic viruses distinguished by a cup-shaped morphology. They usually cause diarrhea and vomiting in infants, young children, and older adults. Originally discovered in Sapporo, Japan, in 1977, these viruses are detected by electron microscopy, molecular methods (e.g., RT-PCR), and/or immunologic methods (e.g., ELISA).

Coronaviridae

Coronaviridae is one of seven families within the order Nidovirales. Of the 30 recognized species within the subfamily Coronavirinae, six are found in humans. Two human species are found in the genus *Alphacoronavirus*, and the remaining four belong to the genus *Betacoronavirus*, along with many other mammalian coronaviruses (CoVs). Many new CoVs have been discovered recently and analyzed genetically. This has resulted in hundreds of new CoV genome sequences, which has led to reorganization of the taxonomic structure and the current phylogenetic relationship of the species. CoVs have large, linear, positive-stranded RNA genomes, ranging from approximately 25 to 32 kilobases (kb) in size, and they are enveloped, helical viruses. They were first identified by electron microscopy and were named because the distinctive club-shaped projections on their surface resemble a crown (Fig. 29.20). CoVs infect several different animals; however, most individual strains of virus typically infect only a single animal species. Some can infect more than one related species.

Four strains of CoV are considered endemic to the United States. These strains are associated with upper respiratory tract infections and occasionally lower respiratory tract infections in people of all ages. One strain in particular has been linked to croup in children. CoVs may be responsible for 15% of coldlike infections in adults, but higher seroconversion rates have been seen in children. A few CoVs are responsible for a small percentage of pediatric diarrhea cases. In general, the illness lasts about 1 week, and blood may appear in the stool.

Fig. 29.20 Transmission electron micrograph of the coronavirus. This virus derives its name from the fact that under electron microscopy, the virion is surrounded by a corona, or halo ($\times 100,000$). (Courtesy Fred Murphy and Sylvia Whitfield, Centers for Disease Control and Prevention, Atlanta, GA.)

A novel CoV was the causative agent of a pandemic respiratory disease that emerged from Hong Kong in late 2002. During a 6-month period, the infection spread rapidly to 26 countries in Asia, Europe, South America, and North America. The virus infected at least 8000 people and resulted in a mortality rate of approximately 10%. The disease was characterized by high-grade fever, pneumonia, and in some patients, acute respiratory distress syndrome (ARDS). The disease was ultimately termed *severe acute respiratory syndrome* (SARS), and the causative agent was designated as the SARS-associated CoV (SARS-CoV). No vaccine or antiviral agent was available to fight the pandemic, which was ultimately ended through intense public health intervention, including massive screening programs, voluntary quarantine, and travel restrictions. This human infection apparently started as a CoV that jumped from its natural animal host, possibly a civet cat, to humans. SARS-CoV highlights the public health risk that can occur when animal viruses suddenly appear in a susceptible human population.

In 2012, a SARS-like virus was linked to severe respiratory tract infections in the Middle East. This virus was named the Middle East respiratory syndrome CoV (MERS-CoV). By August 2013, MERS-CoV was associated with 94 infections and 46 deaths, primarily in Saudi Arabia. MERS-CoV is unlike any other CoV that infects humans. In 2014, another outbreak of MERS-CoV occurred in Saudi Arabia, with 14 people infected and 4 reported deaths. As of July 2022, over 2600 cases and 858 confirmed deaths of MERS-CoV infection in 27 countries have been reported.

The 2002 SARS outbreak created much interest in understanding the epidemiology, reservoir-host relationship, and vaccination possibilities associated with this CoV. In 2007, SARS-CoV antibodies were detected in 47 of 705 South African and Democratic Republic of the Congo bat sera samples collected from 1986 to 1999. Researchers tested bats from the Rocky Mountain region in 2006 and detected CoV RNA in two species of bats: *Eptesicus fuscus* and *Myotis occultus*. Animals, such as civets, can acquire infections with SARS-like CoV from contact with infected bats. Current data indicate that bats, primarily horseshoe bats, are the most likely reservoir for SARS-CoV, although the bat CoVs are species specific. More than 10 mammalian species have been identified as being susceptible to SARS-CoV by natural or experimental infection. Infections of these secondary hosts may give rise to strains that could potentially infect humans.

On December 31, 2019, the existence of patients with pneumonia of an unknown etiology was reported to the WHO by national authorities in China. It was first seen in Wuhan, China, and was thought to have emerged in a food market. This virus was officially identified by the coronavirus study group as SARS coronavirus 2 (SARS-CoV-2), and the resulting outbreak of a coronavirus-associated acute respiratory disease was named coronavirus disease 19 (COVID-19).

From China, COVID-19 rapidly spread into Europe. The first reported case in the United States was on January 21, 2020, in Washington state in a 35-year-old male patient who had just returned from Wuhan, China. On February 20, 2020, the CDC announced that the first person in the United States had died from COVID-19. By July 2022, the WHO reported that the COVID-19 pandemic resulted in over 577,000,000 confirmed cases and over 6,400,000 deaths worldwide. For the same time period, the CDC reported over 90,000,000 U.S. cases with over 1,000,000 deaths.

This virus is highly infectious, and although most individuals are asymptomatic or have mild symptoms, those with certain medical conditions often progress to severe, life-threatening illness. High-risk conditions include diabetes, overweight or obesity, history of smoking or cancer, and heart and kidney disease. Severe illness is linked to two primary causes: secondary pneumonia and an overexuberant proinflammatory cytokine response. This cytokine response is referred to as a *cytokine storm* or *hyperinflammation*. Cytokine storm syndrome is an uncontrolled activation and amplification of the host immune response resulting in the release of several cytokines such as tumor necrosis factor, interleukin-1 (IL-1), IL-6, and IL-18. The cytokine response appears to be related to the severity of ARDS, which is a type of respiratory failure characterized by widespread inflammation in the lungs.

SARS-CoV targets the epithelial cells of the respiratory tract and is transmitted from person to person by direct contact, droplet, or airborne routes. Other organ systems affected by SARS include the spleen, lymph nodes, digestive tract, urogenital tract, CNS, bone marrow, and heart. The virus can also be isolated from urine and feces, suggesting other potential routes of transmission. The receptor for SARS-CoV-2 is angiotensin-converting enzyme 2. This enzyme is expressed on many human cells including those in the respiratory airways, intestine, kidney, heart, and pancreas. Certain individuals may be genetically more susceptible to SARS than others.

CoVs are extremely fragile and difficult to culture, but it is

Case check 29.1

History of leukemia and hypogammaglobulinemia and advanced age placed the patient in the Case in Point at high risk for severe COVID-19. Fortunately, the two treatments of SARS-CoV-2 convalescent plasma he received helped him to remain asymptomatic. However, he was culture positive for the virus several weeks after his diagnosis.

possible to detect viral antigens from some species directly by IF or ELISA (EUROIMMUN Medical Laboratory Diagnostics, Lübeck, Germany). Viral particles can also be detected by electron microscopy in stool samples. However, sensitivity is generally lower with electron microscopy and antigen detection than RT-PCR. The most common diagnostic approach for the identification of CoVs is amplification and detection of virus-specific RNA using RT-PCR. RT-PCR assays have demonstrated greater sensitivity and specificity and a much shorter TAT. Many viral panels are now available for the detection of the four endemic CoVs found in the United States—CoV 229E, CoV HKU1, CoV NL63, and CoV OC43—from respiratory specimens (FilmArray, BioFire Diagnostics). Other nucleic acid-based tests include isothermal amplification methods and loop-mediated amplification assays. These are typically used in research or larger reference laboratories. Antibodies can be detected through western blot analysis and ELISA. Although serologic assays have largely been replaced by NAATs, they still have a role in epidemiologic studies. The COVID-19 pandemic has resulted in an expansion of testing for CoV-2. However, at time of publication, all testing for detection and exposure has EUO authorization from the FDA and CDC.

The treatment of COVID-19 has been based on providing basic life support and mitigating the effects on the respiratory

system caused by ARDS, which is the leading cause of mortality. Modulating cytokine levels is key in preventing widespread organ damage, respiratory failure, and death. Several drugs with antiinflammatory activity in other illnesses were evaluated in respect to their potential utility in the treatment of the hyperinflammation induced by SARS-CoV-2 infection, and these included interferon, steroids, atazanavir, favipiravir, lopinavir-ritonavir, anakinra, baricitinib, and remdesivir. The current preferred therapy in most cases is ritonavir-boosted nirmatrelvir (Paxlovid). The anti-inflammatory agent dexamethasone is used in severe cases. Heparin is added in cases with coagulopathy.

Multiple COVID-19 vaccines were developed, and two successful vaccines were approved for EUO authorization in December 2020. These vaccines are unique in that they use messenger RNA (mRNA) coding for a viral protein. After injection, cells in the recipient use the mRNA to express the viral spike protein, which initiates the immune response to the virus. Although these vaccines are new, mRNA vaccine technology began in the 1980s.

Filoviridae

The family Filoviridae includes eight genera; *Marburgvirus* and *Ebolavirus* are the most clinically significant. The genus *Marburgvirus* contains one species (*Marburg marburgvirus*) and two viruses: Marburg virus (MARV) and Ravn virus. The genus *Ebolavirus* contains five viruses: EBOV, Sudan virus (SUDV), Reston virus (RESTV), Tai Forest virus, and Bundibugyo virus. Both Marburg virus and EBOV share a common morphology (Fig. 29.21) and similar genome and structural proteins. These viruses have many similarities; they rarely cause human infections, they cause infections with high mortality rates, and they have unknown reservoirs in nature, although human infection can result from contact with infected monkeys.

Lake Victoria Marburg virus, now known as MARV, was named after the location of one of the first outbreaks: Marburg, Germany. In 1967, 32 people from Marburg and Frankfurt, in Germany, and from Belgrade, Serbia, and Yugoslavia contracted an unknown infection, and 7 died. Epidemiologists noted that the deceased individuals all worked in vaccine-producing facilities and had contact with African green monkeys

Fig. 29.21 Transmission electron micrograph of an Ebola virus (×100,000). (Courtesy Fred A. Murphy, Centers for Disease Control and Prevention, Atlanta, GA.)

that had arrived recently from Uganda. The virus had been transmitted to 24 other people through healthcare-associated transmission, casual contact, and sexual contact. Patients with secondary infection had a milder illness, and all survived the infection. Outbreaks of MARV are rare.

The EBOVs are named after the Ebola River in the Democratic Republic of the Congo, where the infection first emerged in 1976. The virus emerged almost simultaneously in Sudan. In Zaire, a patient treated at a village hospital for a bloody nose probably introduced the virus into the hospital, where it was then transmitted nosocomially and via contact with individuals at home. Nuns in the hospital routinely reused syringes without sterilizing them. Therefore the hospital amplified the number of cases. Infections were also passed to the victims' families, often during a process in which the intestines of infected deceased males were cleansed to prepare the bodies for funerals.

The two simultaneous outbreaks of Ebola fever were caused by two different viruses, Ebola Zaire, now called *Ebola virus*, and Ebola Sudan, now called *Sudan virus*. Of the two, EBOV is the more virulent. In the initial outbreak, 318 individuals were infected in Zaire; the mortality rate was 88%. In the Sudan outbreak, 284 people were infected, and a mortality rate of 53% was reported. After the initial two large outbreaks, smaller outbreaks occurred. In Sudan, 34 cases occurred in 1979, and 65% of the 34 patients died. The virus seemed to retreat into the jungles for the next 15 years.

An unusual sequence of events occurred in 1989, when monkeys imported to Reston, Virginia, from the Philippines were afflicted by an epidemic of infection by what eventually became the third type of EBOV, RESTV. Four workers in the animal facility developed antibodies to RESTV but did not develop the disease. RESTV was isolated from the bloodstream of one of the workers. EBOV continued to emerge periodically in the Democratic Republic of the Congo (2003 and 2007), southern Sudan (2004), and Uganda (2007). In 2012, several more outbreaks were reported. Beginning in March 2014, West Africa had the largest outbreak of EBOV in history. Multiple countries were involved, with Liberia, Sierra Leone, and Guinea affected the most through early 2016. According to the CDC, there were 28,652 probable cases, with 15,261 laboratory confirmed cases and 11,325 deaths during this outbreak. This outbreak resulted in precautions in both Europe and the United States to handle suspected cases of infected people traveling from West Africa. Many clinical laboratories have now established protocols to handle suspected cases, ensuring safely for both staff and other patients. Newer molecular testing is being developed to detect EBOV from serum, and this will likely obtain rapid FDA review and approval.

Symptoms of EBOV and MARV disease are similar, producing a hemorrhagic fever. After an incubation period of 4 to 16 days, there is sudden onset of fever, chills, myalgia, and anorexia. Patients then develop a sore throat, abdominal pain, diarrhea, vomiting, and a maculopapular rash, and they begin to bleed from injection sites and the GI tract. Hemorrhaging in skin and the internal organs may occur as well. Diagnosis of the infection can be made using RT-PCR, IF, or viral culture. However, because of the risk of laboratory infection, biosafety level 3 laboratories are required. Sometimes electron microscopy of clinical samples will yield the characteristic long, rodlike virions.

Flaviviridae

The family Flaviviridae contains several important human pathogens, many of which are zoonotic arboviruses, including Japanese encephalitis virus, dengue virus, yellow fever virus, St. Louis encephalitis (SLE) virus, Zika virus, Kyasanur Forest disease virus, Langat virus, Löping ill virus, Murray Valley encephalitis virus, Omsk hemorrhagic fever virus, Powassan virus, tickborne encephalitis virus, Wesselsbron virus, and WNV. Japanese encephalitis virus is a major cause of encephalitis in Asia and is the most common cause of arboviral encephalitis in the world. Because it is being reported in regions previously free from Japanese encephalitis, including Australia, Japanese encephalitis virus is considered an emerging pathogen. Currently, nearly 68,000 cases of Japanese encephalitis are reported annually. Because most patients are asymptomatic, cases are likely under-reported. Disease ranges from a flulike illness to acute encephalitis. Children are mostly affected by this infection, with mortality as high as 30%; mortality in adults is much lower.

Another important member of the family Flaviviridae is dengue virus, which causes two distinct diseases: classic dengue fever (DF) and dengue hemorrhagic fever (DHF). Worldwide, tens of millions of cases of DF and approximately 500,000 cases of the more serious DHF occur annually. The average mortality associated with DHF is 5%, accounting for 22,000 deaths each year. Most deaths occur in children younger than 15 years. The virus is transmitted by *Aedes* mosquitoes, including *Aedes aegypti* and *Aedes albopictus*. These mosquitoes infest more than 100 countries and bring the risk of DF to 2.5 billion people.

Dengue virus has four serotypes (1 to 4); DF is a relatively mild infection. Patients with DF develop fever, headache, myalgia, and bone pain (resulting in the nickname *break-bone fever*). Some patients also develop a rash. The disease is self-limiting and often resolves in 1 to 2 weeks. Although classic DF is a mild disease, DHF is not. Patients develop DHF after previous exposure to one serotype of dengue virus and are then exposed to one of the other three serotypes. Exposure to two different serotypes of dengue virus appears to be necessary for development of DHF. Patients with DHF develop the symptoms of classic DF, along with thrombocytopenia, hemorrhage, shock, and sometimes death.

Yellow fever, caused by yellow fever virus, is also considered an emerging infection. Although a safe vaccine has been available for decades, about 200,000 cases of yellow fever with 30,000 resulting deaths are reported annually worldwide. The actual incidence may greatly exceed these numbers. The emergence results from increased spread of the mosquito vectors, deforestation of Africa and South America, and increased travel to endemic regions. The vaccine has greatly reduced or eliminated the transmission of yellow fever in some countries. However, yellow fever is still epidemic in parts of Africa and South America, where about 80% of the population must be vaccinated to reduce the impact of the disease.

Patients bitten by mosquitoes carrying yellow fever virus can develop an asymptomatic or acute infection involving fever, myalgia, backache, headache, anorexia, nausea, and vomiting. Most patients experiencing acute disease recover after about 4 days. However, about 15% enter a systemic toxic phase in which fever reappears. The patient develops jaundice (hence the name *yellow fever*) as well as bleeding from the mouth, eyes, nose, stomach, or other areas. The kidneys

may fail, and about 50% of patients in the toxic phase die. The other 50% recover without serious sequelae.

The three different transmission cycles for yellow fever virus are sylvatic, urban, and intermediate cycles. In the sylvatic cycle, yellow fever virus is maintained in monkey populations and transmitted by mosquitoes. Monkeys become sufficiently viremic to pass the virus to mosquitoes as they feed on the monkeys, thus keeping the transmission cycle active. Humans are not the usual hosts when they enter jungle areas in which the sylvatic cycle exists.

The urban cycle occurs in larger towns and cities when infected *A. aegypti* mosquitoes transmit the infection to humans. Because infected humans can continue the transmission when bitten by uninfected mosquitoes, large outbreaks can occur from a single case of yellow fever. The intermediate transmission cycle of yellow fever occurs in smaller villages in Africa. In the intermediate cycle, humans and monkeys are reservoirs, while mosquitoes serve as reservoirs and vectors in the high-morbidity, low-mortality outbreaks. In the intermediate cycle, mosquitoes can transmit yellow fever virus from monkeys to humans, and vice versa. If patients who develop yellow fever from the intermediate cycle travel to larger cities and are bitten by mosquitoes, they can trigger an outbreak of urban yellow fever.

From 2011 to 2020, a total of 103 SLE neuroinvasive disease cases were reported in the United States. Patients with SLE are most likely to be asymptomatic; hence total cases are much higher. While cases are seen from Canada to Argentina, most human cases occur in the United States. Symptomatic patients may develop a fever only, whereas some patients develop meningoencephalitis. The mortality rate of symptomatic patients is 3% to 20%. Unlike many of the arboviral infections, SLE is milder in children than in adults; older patients have the greatest risk of serious illness and death. SLE is transmitted to humans by the bird biting *Culex* mosquitoes. Most infections occur in the summer months.

First isolated and identified in 1937 from a febrile patient in the West Nile district of Uganda, WNV is an ssRNA virus and member of the Japanese encephalitis antigenic complex, like SLE. The virus is transmitted by a mosquito vector between birds and humans. The virus replicates actively inside the avian host; however, the virus does not replicate well in humans, making humans a dead-end host for infection. The incidence of WNV infection in the United States increased during the mid-1990s, prompting the development of a national surveillance system in 1999. In 2003, the CDC documented 9862 human cases of WNV infection in 44 states, the most ever reported in one year. A decline followed in 2011 to 712, the lowest number of cases ever reported. The number of cases has fluctuated since then. In 2019, a total of 971 cases were reported, and 633 were described as neuroinvasive. A total of 60 patients (9%) with neuroinvasive disease died. From 1999 to 2019, overall, about 16% of the cases were in California and 13% in Texas.

Approximately 80% of individuals infected with WNV are asymptomatic. The remaining 20% display symptoms of what is termed *West Nile fever*, which includes fever, headache, fatigue, occasional rash on the trunk, swollen lymph glands, and/or eye pain. The primary risk factor for serious neuroinvasive disease is age greater than 50 years. Neuroinvasive disease typically manifests as meningitis or encephalitis.

Laboratory tests approved for the detection of WNV include IgG and IgM ELISA, including a rapid WNV ELISA assay and an indirect IF assay for antibodies. WNV ELISA assays can cross-react with other flaviviruses and should be confirmed by antibody neutralization. IgM antibody does not cross the blood-brain barrier; therefore the presence of IgM in CSF strongly suggests CNS infection. WNV can be present in tissues, blood, serum, and CSF of infected humans or animals. Several RT-PCR, TaqMan, and nucleic acid sequence-based amplification assays have been used for confirmation of WNV infection. There is no specific treatment for WNV infection, but in severe cases requiring hospitalization, supportive care, including IV fluids, respiratory support, and prevention of secondary infection, may be warranted.

Zika virus is an insect vector-borne disease that is most commonly transmitted through *Aedes* (*A. aegypti* and *A. albopictus*) mosquitoes. Zika virus can also be transmitted by exposure to infected blood or sexual contact. Less commonly, Zika virus can be transmitted from a mother to a child during pregnancy. Zika virus is typically endemic to parts of Africa and Asia. However, in 2015 to 2016, an epidemic occurred across South, Central, and North America, where the disease was previously unreported. Almost 500,000 cases of Zika virus infection were reported in 38 countries throughout the Americas. Almost 50,000 of these cases were laboratory confirmed, and 360,000 cases were suspected to be positive. In 2016, the CDC reported more than 5000 cases of Zika virus infection, with 95% of the cases in travelers returning from affected areas. Reported cases have dropped significantly since then, with only 4 cases found in the United States and 57 cases in U.S. territories in 2020.

Symptoms of Zika virus infection in most people resemble those of infections with other arboviruses, such as chikungunya virus (primarily fever, headache, and fatigue). The epidemic in Brazil between 2015 and 2016, resulting in over 300,000 cases, was marked by the detection of the virus in fetal amniotic fluid and an increased reporting of cases of *microcephaly* (small head size) in newborns.

Orthomyxoviridae

The influenza viruses are enveloped and belong to the family Orthomyxoviridae. These viruses are distinguished by using two major structural proteins: matrix protein (M) and nucleoprotein (NP). This places the influenza viruses into four genera within the family: *Influenzavirus A*, *Influenzavirus B*, *Influenzavirus C*, and *Influenzavirus D*. Influenza viruses have a worldwide distribution and originate as zoonotic infections, carried by several different species of birds and mammals. The influenza season in the southern hemisphere is from May to October and in the northern hemisphere is from November to April.

Influenza A virus remains one of the most crucial health problems worldwide. In the pandemic of 1918 and 1919, influenza infected an estimated 500 million people, about one third of the world's population, and killed at least 50 million people, including more than 600,000 in the United States. However, since that event, the world has only been able to react to the threat of influenza, rather than vanquish it. A typical influenza season in the United States hospitalizes almost 700,000 and kills about 36,000 people.

Influenza viruses are enveloped; types A and B have eight segments of ssRNA, while types C and D have seven. Influenza A viruses are classified into subtypes using the two major surface glycoproteins: hemagglutinin (H) and neuraminidase (N). The H antigen is used to bind to host cells, and the N antigen cleaves budding viruses from infected cells. The H protein is the major antigenic determinant detected by antisera. There are 17 H antigens (H1 to H17), although human infections usually occur only with H1, H2, and H3. There are 10 N antigens (N1 to N10); human infections usually occur with N1 and N2.

The key to the persistence of influenza virus is its antigenic variation. Each year, antigenic drifts are caused by RNA replication errors of the virus. **Antigenic drift** is a minor change in antigenic structure as mutations accumulate. Antigenic drift occurs with all four influenza viruses—A, B, C, and D. The surface antigens sometimes can change drastically, causing an **antigenic shift**, resulting in a new H or N antigen. Antigenic shift is associated only with influenza A virus. There are two mechanisms of antigenic shift. The first is genetic reassortment of the eight ssRNA strands of two separate influenza strains. Pigs have receptors for both avian and human influenza viruses as well as swine influenza viruses and can be co-infected with all three types of viruses. Reassortment occurs when the genomes of different influenza viruses combine into a single virion, resulting in a new strain of influenza virus. The second mechanism is an adaptive mutation, in which a novel virus slowly adjusts and becomes transmissible from a mammalian (including human) host. Shifts result in novel strains of influenza virus, so the human population is likely to have little or no historic exposure or resistance to the new strain, which greatly increases the risk of pandemics.

Three major shifts occurred during the 20th century. Infection with influenza A virus (H1N1), the *Spanish flu*, appeared in 1918 to 1919. H1N1 was the predominant strain until a shift to influenza A virus (H2N2) occurred in 1957 to 1958. This shift resulted in the *Asian flu* pandemic. In 1968, another shift occurred, and a pandemic strain of influenza A virus (H3N2) resulted in the *Hong Kong flu*. The dominant strains of influenza A virus since 1977 have been influenza A viruses H1N1 and H3N2.

In 1998, an outbreak of infection with influenza A virus (H5N1), the *avian flu*, appeared in poultry in Hong Kong. At least 18 humans acquired the disease via contact with birds that year, and 6 deaths were reported. H5N1 is a highly pathogenic avian influenza (HPAI) virus; historically, most human infections are acquired after direct or close contact with infected birds. The H5N1 influenza virus appeared in flocks in parts of Asia in 2004 and again in 2005, resulting in large poultry losses in Japan, Cambodia, China, Vietnam, and nearby countries. Some humans were infected during these poultry outbreaks. Again, the incidence of human disease was low, but the mortality rate was high, although it is possible that some mild cases went undiagnosed.

Studies documented wide dissemination of influenza A virus (H5N1) throughout Asia because of migrating birds. By early 2006, influenza A virus (H5N1) had been isolated from birds in Turkey, Greece, Italy, Germany, Iran, Iraq, Nigeria, and many other countries. In April 2013, a novel avian flu caused by influenza A virus (H7N9) was reported in China. Only a few cases were reported initially, but 5 of the 11 human cases were fatal. Human-to-human transmission was not

documented. The potential for the avian viruses to adapt to the human host, through genetic reassortment or adaptive mutation, remains an important concern for future influenza seasons.

In the spring of 2009, a highly infectious novel form of influenza, *swine flu*, caused by influenza A virus (H1N1) emerged. It was first reported throughout Mexico and forced school closings and cancellation of sporting events. By October 2009, the WHO had received reports of more than 375,000 human cases and 4525 deaths. Because many countries stopped counting individual cases, the actual number was much larger. The outbreak quickly reached phase 6, which is the WHO definition of a pandemic. This was the first influenza pandemic in 40 years. In April 2010, the WHO announced that the H1N1 influenza virus had moved into the post-pandemic period. H1N1 was found to contain RNA from avian, human, and porcine strains of the virus.

In 2011, human infections caused by influenza A H3N2v, a nonhuman influenza virus variant normally found in swine, were reported. When viruses that normally circulate in animals infect humans, they are termed *variant viruses*. This H3N2v virus was first detected in January 2011, and it had genes from avian, porcine, and human viruses and the 2009 H1N1 pandemic virus M gene.

Because the H and N antigens of influenza A virus continually change, the CDC and the WHO make recommendations for the composition of the quadrivalent influenza vaccine several months before the influenza season begins. The current U.S. vaccine usually contains two different influenza A virus strains, H1N1 and H3N2, and two influenza B virus strains. Influenza B virus infections, which also can occur seasonally, are usually less common than influenza A virus infections, although epidemics of influenza B virus infections can occur every few years. It is highly recommended that persons with reduced immune status (e.g., those with HIV, those with diabetes, and older adults) be vaccinated annually with the inactivated virus vaccine to prevent infection, because it can be rapidly fatal in these populations. A pediatric version for children 6 to 35 months is available. The use of an attenuated quadrivalent intranasal vaccine is only recommended for individuals between 2 and 49 years of age who are in good health.

Influenza C virus can cause mild upper respiratory tract illness in humans, indistinguishable from the common cold. Its genome consists of seven ssRNA segments, lacking the gene coding for neuraminidase, as in influenza A and B viruses. Studies have shown influenza C virus to be more stable genetically compared with influenza A virus, and although reassortment does occur in the former, it is less prone to major changes in infectivity. The influenza D virus was isolated from a pig in Oklahoma in 2011. Subsequently, it has been isolated from other animals. Little is known about its likelihood to cause human infections.

Influenza viruses are spread through aerosol inhalation. Infection may also be spread by handling fomites. Viruses attack the ciliated epithelial cells lining the respiratory tract, causing necrosis and sloughing of the cells. The incubation period is 1 to 4 days. Although asymptomatic infections can occur, infections are usually characterized by cough, sore throat, rapid onset of malaise, fever, chills, myalgia, and often a nonproductive cough. The fever can be as high as 41° C (105.8° F). Infected patients are ill for as long as 7 days, and

convalescence may require more than 2 weeks. Influenza can also cause a fatal viral pneumonia. Complications include secondary bacterial pneumonia.

The best specimens for diagnosis are nasopharyngeal swabs, washes, or aspirates collected early in the course of the disease. Flocked swabs (Copan Diagnostics, Corona, CA) are reported to collect significantly more epithelial cells from the nasopharynx compared with rayon swabs. Specimens should never be frozen. Several rapid kits are commercially available for the diagnosis of influenza in about 30 minutes. Some of these kits are of low complexity and are waived by the CLIA. Some kits can detect and distinguish between influenza A and B viruses, but some cannot distinguish between them or detect only influenza A virus. These tests are valuable in outpatient settings, and their low cost and ease of use make them ideal for quick screening. Influenza virus can also be identified in respiratory secretions by using DFA, EIA, and immunochromatographic assays.

Nucleic acid–based assays are also used for the detection of influenza viruses, with the most common method being RT-PCR. These assays are fast becoming the method of choice for detection. Some can be completed in less than 30 minutes, have a low cost, and are easy to perform. They can be used as point-of-care tests, thus improving patient care.

Influenza viruses grow in the amniotic cavity of embryonated chicken eggs and various mammalian cell culture lines, such as PMK and MDCK cells. Influenza-infected culture cells adsorb RBCs, a feature that can be used to detect positive cell cultures. Positive cultures can be detected rapidly using IF staining of infected monolayers grown in shell vials or flat-bottomed wells of microtiter plates.

The antiviral drugs amantadine and rimantadine can prevent infection or reduce the severity of symptoms if administered within 48 hours of onset of infection. These antiviral drugs are effective only against influenza A virus. A newer class of antivirals, termed *neuraminidase inhibitors*, is available. These agents, such as zanamivir (Relenza) and oseltamivir (Tamiflu), are more expensive compared with amantadine but provide coverage against infections by influenza A virus and influenza B virus. Current CDC guidelines highly recommend both zanamivir and oseltamivir as primary treatments in confirmed cases of influenza. There has been significant resistance to amantadine by influenza A virus (H3N2), so it is not recommended for treatment of infection by this virus. There have been some reports of resistance to oseltamivir by influenza A virus (H1N1), but use of this agent is still recommended as a primary treatment.

Paramyxoviridae

Parainfluenza viruses

Several genera belong to the family Paramyxoviridae, including *Morbillivirus*, and *Rubulavirus*. Four types (1 to 4) of PIVs cause disease in humans. Human PIV-1 and PIV-3 belong to the genus *Respirovirus*; PIV-2 and PIV-4 belong to the genus *Rubulavirus*. PIVs are enveloped helical RNA viruses with two surface antigens: hemagglutinin-neuraminidase (HN) antigen and fusion (F) antigen. HN antigen is the viral adhesion molecule; F antigen is responsible for the fusion of the virus to the cell and of one infected cell to another infected cell.

PIV-1 infections occur most often in the fall every other year, and the incidence of PIV-2 is generally lower than that of

PIV-1 and PIV-3. PIV-2 is seen every 2 years alternating with PIV-1. PIV-3 occurs almost every year in spring and summer and can be seen yearlong in temperate climates. PIV-4 is seldom isolated, but routine testing is not readily available.

PIVs are a primary cause of respiratory disease in young children. PIV-1 and PIV-2 cause the most serious illnesses in children between 2 and 4 years of age. PIV-1 is the primary cause of croup (laryngotracheobronchitis) in children. PIV-3 causes bronchiolitis and pneumonia in infants and is second in importance only to RSV. PIV-4 generally causes mild upper respiratory tract infections. The viruses are spread through respiratory secretions, aerosol inhalation, and direct contact. Infection of the cells in the respiratory tract leads to cell death and an inflammatory reaction in the upper and lower portions of the respiratory tract. Rhinitis, pharyngitis, laryngotracheitis, tracheobronchitis, bronchiolitis, and pneumonia can result.

Direct examination of nasopharyngeal secretions by IF can give rapid results. Some newer nucleic acid assay panels now include PIV-1, PIV-2, and PIV-3, which aid in treatment and epidemiology efforts. Most of these newer PCR technologies are on panels that include several other respiratory pathogens. Serologic assays are more valuable for epidemiologic studies than for diagnostic purposes. The best specimens for viral culture are aspirated secretions and nasopharyngeal washes. Specimens for viral isolation should be taken as early in the illness as possible, kept cold, and inoculated into PMK cells or LLC-MK2 cells. The viruses can be identified by using hemadsorption, IF, or EIA techniques. Aerosolized ribavirin can be used to treat infection. No vaccines are available, and infection control measures like those for RSV are used to prevent spread in health care facilities.

Mumps virus

Mumps virus is related to PIVs and is in the genus *Rubulavirus*. It is an enveloped virus with HN and F surface antigens. Mumps virus, which has a global distribution, is spread through droplets of infected saliva. It causes an acute illness producing unilateral or bilateral swelling of the parotid glands, although other sites, such as the testes, ovaries, and pancreas, can be infected. The virus infects primarily children and adolescents and usually results in long-lasting immunity. The primary infection of the ductal epithelial cells in the glands results in cell death and inflammation.

A vaccine effective in controlling the disease is available. Two doses are recommended for better immunity—the first at 12 to 15 months and the second at 4, 6, 11, or 13 years of age. The annual incidence of mumps in the United States varies. From 2000 to 2020, cases ranged from about 200 to over 6000. Only 154 cases were reported in 2021. Large multistate outbreaks of over 6000 mumps cases were documented in 2006, 2016, and 2017. The reasons for the outbreaks remain largely unknown. They have occurred in communities of individuals who received one or two vaccines. Outbreaks are generally seen in close-contact settings. During the outbreak of 2016 to 2017, most cases (nearly 3000) occurred in a close-knit community in northwest Arkansas. From 2009 to 2010, another outbreak, with 3502 cases in a New York camp, was reported and seemed to confirm waning immune protection by the vaccine.

The mumps virus can be isolated from infected saliva and swabbing of the Stensen duct, from 9 days before onset of symptoms until 8 days after parotitis appears. The virus, which is relatively fragile, can also be recovered from urine

and CSF. Specimens may be examined directly by using IF and EIA methods. Studies have shown viral isolation using shell vial cultures of Vero or LLC-MK2 cells to be more successful than those with HEp2 or HeLa cell lines. Isolates can be identified by hemadsorption inhibition, IF, and EIA tests.

Paired sera can be tested for mumps antibody by EIA, IF, and hemagglutination inhibition tests. Paired sera taken at as small an interval as 4 to 5 days can demonstrate a diagnostic or fourfold increase in titer. Cross-reactions between soluble and viral antigens can confuse the interpretation of serologic results. Virus isolation is preferable, although primary health care providers rarely have trouble recognizing mumps clinically.

Measles virus

The measles virus is an enveloped virus classified in the genus *Morbillivirus*. It is found worldwide; in temperate zones, epidemics occur during winter and spring. At one time, measles (rubeola) was the most common viral disease in children in the United States. An average of 500,000 cases of measles were reported annually in the 1950s, with an average of 500 deaths. Immunization programs began in the United States in 1963, and the reported number of cases decreased to fewer than 1500 by 1983. A reemergence of measles occurred in 1989 to 1991, attributed to immigration and lack of vaccination. The decision to administer a second dose of vaccine to school-age children has drastically reduced the incidence of measles in the United States. From 2010 to 2021, the number of cases has ranged from 13 to 667. The WHO reported a 50% surge in measles cases from 2016 to 2019, with 869,770 total cases and 207,500 deaths. This is the highest number of reported cases since 1996.

Measles is highly contagious and spreads by aerosol. Initial replication takes place in the mucosal cells of the respiratory tract. The measles virus then replicates in the local lymph nodes and spreads systemically. The virus circulates in T and B cells and monocytes until eventually the lungs, gut, bile duct, bladder, skin, and lymphatic organs are involved. After an incubation period of 7 to 10 days, there is an abrupt onset, with symptoms of sneezing, runny nose and cough, red eyes, and rapidly increasing temperature. About 2 to 3 days later, a maculopapular rash appears on the head and trunk. **Koplik spots**, lesions on the oral mucosa consisting of irregular red spots with a bluish-white speck in the center (Fig. 29.22),

Fig. 29.22 Patient presenting on the third pre-eruptive day with Koplik spots indicative of the onset of measles. (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

generally appear 2 to 3 days before the rash and are diagnostic. Complications such as otitis, pneumonia, and encephalitis may occur. A progressive, highly fatal form of encephalitis can occur but is rare. In developing countries with malnutrition and poor hygiene, measles can have a high fatality rate. Infection confers life-long immunity. An effective attenuated vaccine is available and recommended for all children.

Measles is easily diagnosed clinically, so few requests for laboratory identification are made. The virus is fragile and must be handled carefully. The specimens of choice are from the nasopharynx and urine, but the virus can be recovered from these sources only in the early stages of infection. The virus grows in PMK cells, causing the formation of distinctive spindle-shaped or multinucleated cells. Virus isolates can be identified by using serum neutralization, EIA, or IF tests. Serologic diagnosis of measles is accomplished by demonstrating measles-specific IgM in the specimens collected during the acute phase of the disease. Nucleic acid testing should be considered for diagnostic use if IgM testing is compromised by the recent use of measles virus-containing vaccine as part of a routine vaccination or in response to a suspected outbreak.

Respiratory syncytial virus

RSV, a member of the genus *Orthopneumovirus*, causes croup, bronchitis, bronchiolitis, and interstitial pneumonia. It is the most common cause of severe lower respiratory tract disease among infants and young children worldwide. Almost one half of all infants are infected by RSV during their first year of life, and almost all have been exposed to RSV by 2 years of age.

The CDC estimates 2.1 million outpatient visits among children younger than 5 years of age, 58,000 hospitalizations, and 14,000 deaths annually. Because infection does not confer complete immunity, multiple infections can occur throughout life and can be severe in older adults, the immunocompromised, and those with cardiac and respiratory problems. It is estimated that 24 of 1000 children with RSV infection will be hospitalized. For this reason, healthcare-associated RSV is a problem in many medical facilities. Recommendations to reduce the risk of healthcare-associated spread include testing hospital personnel and infants with upper respiratory tract infections for RSV, isolating infants with RSV infection, following good handwashing and personal protective equipment practices, limiting visitation, and organizing patients and staff members into cohorts.

RSV can be a significant cause of morbidity and death in older patients. With a rapidly growing aging population, RSV in elder care facilities is becoming a significant problem in the United States. Unlike the bronchiolitis caused by RSV in children, pneumonia often develops in adults. The virus spreads mostly through large-particle droplets and contact with fomites rather than through inhalation of small aerosols. The virus may be carried in the nares of asymptomatic adults. RSV infections occur in yearly outbreaks that last 2 to 5 months and usually appear during winter or early spring in temperate zones.

RSV can be identified in specimens from nasopharyngeal swabs and washes by using DFA or EIA. Rapid antigen detection kits are also available for RSV, but they have a relatively low sensitivity. Several NAATs are available for RSV testing, with most taking less than 1 hour to provide results. These are normally part of a multiplex assay for other respiratory

pathogens. Because the virus is extremely fragile, recovering it from cultures is difficult, but culture remains the gold standard. It is important to collect samples within the first few days of illness. In about 50% of cases, antigen detection and viral cultures are negative at 1 week. Specimens for culture must be kept cold but cannot be frozen. RSV grows readily in continuous epithelial cell lines, such as HEp2, forming syncytia. It also grows in PMK and human diploid fetal cells. Once the CPE is detected, RSV can be identified by using IF, EIA, and serum neutralization tests.

The antiviral compound ribavirin is approved for treatment of RSV infection. However, some controversy regarding the efficacy of ribavirin therapy still exists. A monoclonal antibody, palivizumab (PVZ), which blocks RSV entry into the host cell, is also approved for RSV treatment and prophylaxis in high-risk children. Often, ribavirin is recommended to be used in combination with PVZ. No vaccine for RSV infection is available.

Human metapneumovirus

Human metapneumovirus (HMPV) was first described in children with previously virus-negative cultures in 2001. Infected children display many clinical symptoms that mimic infections with RSV, influenza virus, and PIV. Often, these diseases are ruled out early in diagnosis, which leads to a presumptive identification of HMPV. Serologic and RNA sequence studies have shown that the virus is found worldwide in all age groups. Most children have been exposed by the time they reach 5 years of age. One half of the lower respiratory tract infections seen in children in the first 6 months of life are caused by this virus. Clinical disease ranges from mild upper respiratory tract infection to acute lower respiratory tract infection and includes fever, nonproductive cough, sore throat, wheezing, congestion, shortness of breath, and lethargy. HMPV infections usually occur in the winter months, but outbreaks have been documented during summer.

HMPV infections usually occur in children. A survey in Finland among 1338 children younger than 13 years of age found that 47 (3.5%) with respiratory illness were positive for HMPV. The highest concentration of illness (7.6%) was seen in children younger than 2 years of age. Co-infections with another virus, including enterovirus, rhinovirus, influenza virus, and PIV, were detected in eight (17%) of the infected children. HMPV has also been documented to cause outbreaks in long-term care facilities. In the summer of 2006, HMPV affected 26 residents and 13 staff members in a 171-bed California long-term care facility. All affected residents had an underlying medical condition; two were hospitalized, but none died. This outbreak indicates a year-round risk of infection in institutionalized older adults. Treatment for HMPV infection is mostly supportive.

Specimens for detecting HMPV can be collected from the nasopharynx by using flocked swabs placed in transport media and transported to the laboratory for culture or molecular analysis. Specimens should be processed immediately but can be stored at 4°C for up to 72 hours. DFA and RT-PCR assays are used for identification, although DFA has lower sensitivity. The respiratory viral panel assay from Luminex Molecular Diagnostics (Toronto, Canada) claims 100% sensitivity and 98.2% specificity for identification of HMPV in clinical specimens. HMPV grows slowly in standard cell culture lines, such as monkey kidney and A549 cell lines.

BOX 29.1 Genera within the family Picornaviridae of human significance

Genus <i>Aphthovirus</i>
Foot and mouth disease virus
Genus <i>Enterovirus</i>
Enteroviruses species A to D (about 106 types)
Polioviruses types 1 to 3
Echoviruses
Human coxsackieviruses
Rhinovirus species A to C (about 165 types)
Genus <i>Parechovirus</i>
<i>Parechovirus</i> species A and B (about 24 types)
Genus <i>Hepatovirus</i>
Hepatitis A virus

Picornaviridae

Picornaviridae is one of the largest families of viruses, with more than 280 members. It contains many important human and animal pathogens. Four genera with human clinical significance belong to the family Picornaviridae: *Aphthovirus*, *Enterovirus*, *Hepatovirus*, and *Parechovirus* (see Box 29.1). The genus *Hepatovirus* includes HAV. This virus is discussed in detail in the “Hepatitis Viruses” section later in this chapter.

Enteroviruses

These small naked viruses cause various conditions, including fever of unknown origin, aseptic meningitis, paralysis, sepsis-like illness, myopericarditis, pleurodynia, conjunctivitis, exanthemas, pharyngitis, and pneumonia. Enteroviruses have also been implicated in early-onset diabetes, cardiomyopathy, and fetal malformations.

Most serotypes of the enteroviruses are distributed worldwide. In temperate zones, enterovirus epidemics occur in summer and early fall. Enterovirus infections are more prevalent in areas with poverty, overcrowding, poor hygiene, and poor sanitation. Viruses are spread via aerosol inhalation, the fecal-oral route, and fomites. The portal of entry is the alimentary canal via the mouth. The viruses replicate initially in the lymphoid tissues of the pharynx and gut. Viremia can result in the virus spreading from these locations to the spinal cord, heart, and skin. The clinical disease caused by enteroviruses can be neurologic, respiratory, or cardiac, depending on viral spreading and the immune status of the host. Enterovirus infections most often cause mild nausea and diarrhea in adults. However, disease can be much more severe in neonates because of their immature immune system.

The polioviruses tend to infect the CNS and cause paralysis in a small percentage of infected individuals. The viruses destroy their host cells. In the intestines, damage is temporary because the cells lining the gut are rapidly replaced. In contrast, neurons are not replaced, which results in neuron death and permanent paralysis.

No vaccines are available for enteroviruses other than poliovirus. Good personal and health care facility hygiene and proper sanitation can reduce the incidence of enterovirus infections. Poliovirus vaccines of attenuated or inactivated viruses are available. Since 1988, the polio vaccine program has been crucial to the WHO's effort to eradicate polio worldwide. In countries where polio is considered to have endemic rates of incidence, there has been a steady decrease since

the program began. In 1988, 125 countries reported endemic rates; by 1999, the number of such countries had decreased to 30, and in 2013 to only 3: Afghanistan, Nigeria, and Pakistan. In 2020, only two countries were considered endemic for wild-type poliovirus: Afghanistan and Pakistan. Unfortunately, interruptions in vaccine programs has caused an increase in cases. The WHO reported 175 cases in 2019, up from only 33 in 2018; transmission continues to be widespread in Pakistan. In 2020, there were 1107 cases of circulating vaccine-derived poliovirus infections; 443 were in the two endemic countries, and 664 were in nonendemic countries.

Enteroviruses can be cultured from pharyngeal specimens immediately before the onset of symptoms and for 1 to 2 weeks afterward; the viruses can be isolated from feces for as long as 6 weeks thereafter. However, ideally, specimens should be obtained early in the course of the infection. Specimens from the throat, feces, rectum, CSF, and conjunctiva are recommended.

Polioviruses, type B coxsackieviruses, and echoviruses grow readily in several cell lines, including PMK, continuous human and primate, and human fetal diploid fibroblast lines. The high-numbered enteroviruses (68 to 71) require special handling. The CPE appears quickly and is readily identifiable. Enteroviruses have no group antigen, so they must be identified individually by a serum neutralization test. The WHO distributes pools of enterovirus antisera that allow identification by neutralization patterns in the antisera. The CPE and resistance to detergent, acid, and solvents constitute a presumptive diagnosis of enterovirus infection.

Hand, foot, and mouth disease (HFMD) is caused primarily by coxsackievirus types A5, A10, and A16 and occasionally by enterovirus type 71. HFMD generally occurs in young children. Outbreaks of HFMD caused by EV71 have been reported, mostly in children in East and Southeast Asia, with some cases seen in Cambodia and China, resulting in the death of hundreds. It is spread by fomites or via the oral-fecal route. A mild prodromal phase can develop, with malaise, headache, and abdominal pain. Small, painful sores suddenly appear on the tongue, buccal mucosa, and soft palate. Simultaneously, a maculopapular rash appears on the hands, feet, and buttocks, followed by bullae on the soles of feet and the palms of hands. The lesions regress in about 1 week. If a rash develops, it is transient. The virus can be isolated from specimens from swabs of the mouth and bullae. Coxsackievirus A16 grows in PMK and human diploid fibroblast cells and can be identified by serum neutralization tests.

More than 150 serotypes of rhinoviruses exist, and they are the major cause of the common cold. Most people experience two to five colds each year, and almost 50% of these colds are caused by the rhinoviruses. Rhinovirus infections occur throughout the year, but their incidence increases in winter and spring. Transmission is primarily via aerosols, but contact with secretions and fomites can also cause infection.

Rhinoviruses infect the nasal epithelial cells and activate the mediators of inflammation. Symptoms include a profuse watery discharge, nasal congestion, sneezing, headache, sore throat, and cough. In severe cases, bronchitis and asthma can result. Unfortunately, no cure for the common cold has been found. Treating symptoms and reducing the spread of the virus in the household is the typical response. Both natural and recombinant interferons have been shown to be effective in preventing infection and illness when given intranasally over short periods. However, prolonged administration has resulted in adverse effects, such as nasal irritation, ulceration, and bleeding.

Case in point

A 36-year-old man was admitted to the hospital after presenting at the emergency department with a self-reported, 7-month history of numbness and weakness in his right leg. He had lost 25 lb, was experiencing bowel incontinence, and had been unable to urinate for 3 days. Two years previously, the patient had been diagnosed with HIV infection. A physical examination demonstrated bilateral lower extremity weakness, and his reflexes were slowed throughout his body. KS lesions were noted, especially on the lower extremities, along with thrush and herpes lesions in the perianal region. The patient had no fever, and magnetic resonance imaging ruled out spinal cord compression. The patient had a history of intravenous drug abuse, chronic diarrhea for 1.5 years, KS for 2 years, and pancytopenia for several weeks. The patient had large right arachnoid cysts of congenital origin. No previous laboratory report indicated infectious agents in the CSF. Meningitis was suspected, and the patient was admitted with a diagnosis of polyradiculopathy (neuropathy of the spinal nerve roots) secondary to AIDS. Blood and CSF were collected. Although numerous white blood cells were found, the CSF produced no growth on routine bacteriologic culture. The blood cultures were also negative. Acyclovir was administered after culture results were received.

Retroviridae

The family Retroviridae contains several subfamilies, including Oncovirinae and Lentivirinae. The retroviruses have a unique mode of replication; they require an RNA-dependent DNA polymerase (reverse transcriptase) to synthesize DNA from the RNA genome. The human T-lymphotropic viruses HTLV-1, HTLV-2, and HTLV-5 belong to the subfamily Oncovirinae. These viruses are not cytolytic but are associated with several leukemias, sarcomas, and lymphomas.

HIV belongs to the subfamily Lentivirinae. Although some groups of individuals, mostly in West Africa, are infected by HIV-2, it is the impact of HIV-1 that continues to be felt around the world. HIV causes AIDS. HIV-1 was identified first and is responsible for the AIDS pandemic. The WHO estimates about 37.7 million people were living with HIV/AIDS at the end of 2020 and approximately 1.5 million new cases were diagnosed. Approximately 680,000 HIV/AIDS-related deaths occurred in 2020. The region most severely affected by HIV/AIDS is sub-Saharan Africa, which has approximately 25.4 million patients with HIV infection, accounting for 67% of the total worldwide incidence. Children share this burden; in 2020, approximately 1.7 million children younger than 15 years of age had HIV/AIDS, and about 150,000 cases of newly infected children were reported.

It was reported that at the end of 2019, an estimated 1.2 million people 13 years of age and older had HIV/AIDS in the United States, and there were 36,801 new HIV cases. Approximately 14% are not aware of their infection. Of the new cases, approximately 81% were men. The greatest number of persons who contract HIV/AIDS are MSM. This group accounted for 70% of the new cases.

The virus is transmitted via blood and exchange of other body fluids. HIV is cell associated, so fewer viruses are found in cell-free plasma than in whole blood, and even fewer viruses are found in saliva, tears, urine, or breast milk. HIV is not highly contagious, and normal, social, nonsexual contact

Fig. 29.23 Human immunodeficiency virus (HIV).

poses no threat to individuals. High risk for contracting the virus includes unprotected sex with multiple partners, IV drug abuse, infusion of blood and blood products, and presence of the virus in a pregnant woman who passes it to the fetus during pregnancy. Individuals with ulcerative sexually transmitted infections (STIs), e.g., syphilis, genital herpes, chancroid, are at greatest risk. Donor blood and blood products are screened for HIV, which substantially reduces the risk.

HIV is a spherical virus, with a three-layer structure (Fig. 29.23). In the center are two identical copies of ssRNA and reverse transcriptase surrounded by an icosahedral capsid. The nucleocapsid is enclosed by a matrix shell to which an envelope of host cell origin is attached. Inserted into the viral envelope are viral glycoprotein (gp) trimers or spikes. The diagnostically important HIV antigens are the structural proteins p24, gp41, gp120, and gp160.

Once HIV enters the body, the primary target cells are the CD4⁺ T cells, monocytes, and macrophages. Acute infections are generally mild and can resemble infectious mononucleosis. The individual will then enter a period of clinical latency, and even though the virus is replicating rapidly in lymphoid tissues, the virus is not detectable in the bloodstream, and the patient remains asymptomatic. Eventually lymphopenia results, with the greatest loss in the CD4⁺ T-cell population. Healthy individuals have CD4⁺ T-cell counts of at least 1000/mm³, whereas patients with HIV/AIDS can have counts lower than 200/mm³. Lymph nodes become enlarged and hyperplastic. The virus destroys the T-helper cells, which are critical in host immune response to infectious agents. The patient begins experiencing several chronic and recurrent infections (Box 29.2). As the disease progresses, the CD4⁺ cell count continues to decline, and the severity of opportunistic infections increases. The patient can also develop virus-induced cancers, such as KS. Death usually occurs because of opportunistic infections, although HIV-1 itself can directly cause encephalitis and dementia.

In adult patients living in developed countries, the average length of time from HIV infection to development of AIDS is about 10 years. About 20% develop AIDS within 5 years, and fewer than 5% have an asymptomatic HIV infection for

BOX 29.2 Common opportunistic infections and cancers in patients with acquired immunodeficiency syndrome

- Candidiasis of the respiratory tract
- Coccidiomycosis
- Cryptococcal meningitis
- Cryptosporidiosis with persistent diarrhea
- Cytomegalovirus infections of organs other than the liver, spleen, or lymph nodes
- Histoplasmosis
- Persistent herpes simplex virus infections including the respiratory tract
- Kaposi sarcoma or lymphoma of the brain in patients older than 60 years of age
- Oral hairy leukoplakia
- Lymphoid interstitial pneumonia, pulmonary lymphoid hyperplasia, or both in children younger than 13 years of age
- Invasive cervical cancer
- *Mycobacterium avium* complex, *Mycobacterium kansasii* infection
- *Pneumocystis jirovecii* pneumonia
- Progressive multifocal leukoencephalopathy
- Toxoplasmosis of the brain in infants younger than 1 month of age
- Wasting disease

Case check 29.2

Clinical manifestations of HIV infection include CNS involvement, opportunistic infections, and tumors. CNS involvement is often seen in HIV-associated dementia complex but can manifest itself as other neurologic problems, such as loss of bowel or bladder control and weakness in the extremities. KS develops from the cells lining the lymph or blood vessels. The resulting lesions are red, purple, or brown blotches or tumors on skin. Other than their appearance, the skin lesions of KS often cause no symptoms. However, in some cases, they may cause painful swelling and be more painful when found in the legs, groin, or skin around the eyes. KS in such sites as the liver, lungs, or digestive tract may be life-threatening because of abnormal bleeding or difficulty breathing.

periods longer than 10 years. The rate at which the virus multiplies in the host is related to the onset of AIDS. This rate can be measured with an HIV viral load assay, a quantitative gene amplification technique that measures the amount of HIV-1 RNA in the plasma.

Laboratory diagnosis of HIV infection is generally based on demonstration of anti-HIV antibodies and, in some cases, detection of viral antigens and RNA. Serologic tests suffer from the disadvantage of the *window period*, the time between infection and the ability to detect antibodies (seroconversion). HIV antibodies are normally produced within a few weeks after infection. The window period varies depending on the assay, but the fourth-generation assays have a median window period of 18 days. Several assays are commercially available as screening tests using different methods, including EIA and IF.

The early diagnostic kits, referred to as *first-generation screening tests*, used purified viral lysate as antigens. The second-generation tests used recombinant viral proteins, thus improving performance. The third-generation tests relied on the double-antigen sandwich assay. In this procedure, viral

antigen attached to a solid-phase bound antibody to HIV from the patient's serum. Labeled HIV antigen was then added, captured by the patient's antibody, and measured. Fourth-generation kits detect antibody and HIV-1 p24 antigen. The first fifth-generation assay is a multiplexed screening test that detects and differentiates three HIV analyte markers: anti-HIV-1 antibodies, anti-HIV-2 antibodies, and the p24 antigen. The immunoassays are generally based on EIA or chemiluminescent immunoassay methods. By detecting antigen, early infections could be identified before antibody is produced. These newest assays are considered the standard of care for diagnosis of HIV infection.

Several rapid assays screen for HIV infection by using serum, plasma, and saliva. By 2012, the FDA had approved six rapid tests for the diagnosis of HIV infection: OraQuick Advance rapid HIV-1/2 antibody test (OraSure, Bethlehem, PA); Uni-Gold Recombigen HIV test (Trinity Biotech, Wicklow, Ireland); Reveal G2 rapid HIV-1 antibody test (MedMira, Halifax, Canada); Multispot HIV-1/2 rapid test (Bio-Rad Laboratories, Hercules, CA); and Clearview HIV-1/2 and Clearview Complete HIV-1/2 (Inverness Medical Professional Diagnostics, Princeton, NJ). OraQuick for whole-blood and oral fluid specimens, Clearview Complete for whole blood, and Uni-Gold for whole-blood samples have waivers from the CLIA. Currently, the FDA has approved one home collection kit, the Home Access HIV-1 test system (Home Access Health Corporation, Maria Stein, OH). In 2012, the first FDA-approved in-home HIV test kit was the OraQuick In-home HIV Test (OraSure Technologies), and by 2016, the FDA had approved multiple tests in each category.

Current CDC guidelines (published in 2014 and revised in 2018) recommend using a screening test that detects HIV-1 and HIV-2 antibodies and p24 antigen. No further testing is required if the test result is negative. Any reactive result on a screening test should be tested with a supplemental antibody immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies. If both tests are reactive, the specimen should be interpreted as positive for HIV. A specimen positive in the initial screening test and negative in the supplemental test should be tested with a NAAT. A positive NAAT indicates an acute HIV infection. A specimen with a negative NAAT should be referred for testing with a different validated supplemental HIV-2 test (antibody test or NAAT) or repeat testing in 2 to 4 weeks. Other immunologic markers of HIV infection are listed in [Box 29.3](#).

The western blot has been the reference method for HIV diagnosis for many years. Viruses grown in cell cultures are lysed, and the proteins are separated by electrophoresis and transferred to nitrocellulose. Antibodies to several HIV proteins and glycoproteins can be detected. For a positive result, CDC guidelines require detection of at least two antibodies

to the three proteins p24, gp41, and gp120/160. Western blot results should also be followed by tests for anti-HIV-2 antibodies ([Fig. 29.24](#)).

Because these viruses readily develop resistance to drugs, HIV infection is often treated with combination therapy. Highly active antiretroviral therapy (HAART) involves aggressive combination therapy soon after HIV infection is diagnosed, ideally within 7 days. In hospital exposures, a similar strategy is used if a health care worker is accidentally exposed to the virus. Aggressive therapy is initiated after the exposure, and this significantly reduces the risk of contracting an infection. Despite aggressive therapy, a cure is not achieved. In 2008, scientists reported that an American living in Berlin (*the Berlin patient*) was cured of HIV infection. The patient received a bone marrow transplant from a donor with a CCR5 mutation (CCR5 Δ 32). CCR5 is a coreceptor for HIV adhesion. The mutation prevents virus infection. Subsequently, two additional patients receiving similar treatment were also reported to be cured, the most recent in 2022. Additional reports of cures in patients receiving HAART have been made; however, these have not been substantiated.

Several classes of antiviral drugs are approved for treatment. Nucleoside reverse transcriptase inhibitors (NRTIs) were the first class of retroviral drugs developed and are incorporated into viral DNA; these include adefovir, azidothymidine, dideoxyinosine, d4T (stavudine), 3TC (lamivudine), and tenofovir. NRTIs inhibit the conversion of nucleoside analogues in the body to nucleotide analogues. Non-NRTIs attach to reverse transcriptase, preventing conversion of RNA to DNA; examples include delavirdine, nevirapine, and

Fig. 29.24 Human immunodeficiency virus immunoblot. Reactive protein (p) and glycoprotein (gp) bands appear as purplish lines across the strip. Proteins with higher molecular weights appear at the top of the strip. Structural and nonstructural proteins are given RNA structural genome codes: GAG for group-specific antigens; POL for polymerase; and ENV for envelope. ENV codes for glycoprotein precursors: gp160, gp120, and gp41 to gp43. POL codes for p65, p51, and p31. GAG codes for p55, p24, and p17. Results are negative, indeterminate, or positive based on the pattern on the strip. Positive corresponds to reactivity to two or more of the following antigens: p24, gp41, or gp120/gp160. Indeterminate corresponds to the appearance of one or more bands in a pattern that does not satisfy the positive criteria. Negative corresponds to the absence of any band on the strips. (Courtesy Patricia A. Cruse.)

BOX 29.3 Important immunologic markers for acquired immunodeficiency syndrome

- Steady decline in number of CD4⁺ T cells
- Depression of the CD4⁺-to-CD8⁺ cell ratio to less than 0.9 (reference value, ≥ 1.5)
- Functional impairment of monocytes and macrophages
- Decreased natural killer cell activity
- Anergy to recall antigens in skin tests

efavirenz. Other classes of antiviral drugs include protease inhibitors (e.g., ritonavir, saquinavir, indinavir, amprenavir), fusion inhibitors (e.g., enfuvirtide), integrase strand transfer inhibitors (e.g., dolutegravir, elvitegravir, raltegravir), and chemokine receptor antagonists (e.g., maraviroc). HAART includes combinations, such as two NRTIs combined with a protease inhibitor.

HIV viral load assays can predict therapeutic efficacy. In different studies, suppression of HIV RNA levels to less than 5000 copies of RNA/mL for up to 2 years was correlated with an increase in CD4⁺ cell counts, up to 90/mm³. In contrast, patients with HIV RNA loads of more than 5000 copies of RNA/mL generally showed a decrease in CD4⁺ cell counts. Usually, these assays are performed monthly so therapy can be adjusted on an individual basis.

Case check 29.3

In HIV infection, the immune system is severely compromised, giving rise to many opportunistic infections caused by viruses, bacteria, fungi, and protozoa, as well as neoplastic disease, wasting syndrome, progressive multifocal leukoencephalopathy, and HIV encephalopathy. These complications often result in death. Meningitis occurs frequently in patients with HIV infection and can be caused by a variety of agents. In the Case in Point, the patient was treated with acyclovir for a presumed HSV meningitis and/or encephalitis. Acyclovir is an inactive nucleoside analogue that is metabolized by viral thymidine kinase into an active form, which results in premature termination of DNA during synthesis.

Rhabdoviridae

Rabies is caused by several strains of viruses belonging to the genus *Lyssavirus* in the family Rhabdoviridae. An estimated 55,000 persons die as a result of rabies worldwide annually, with 40% of these being children younger than 15 years of age. Dogs are implicated in 99% of rabies deaths among humans. In the United States, human cases of rabies are rare, with approximately two per year. However, rabies is an emerging infection in animals, with all mammals being susceptible. Most rabies infections 40 years ago occurred in dogs, with some occurring in cats, foxes, and skunks. However, in the United States, rabies is now more closely associated with wild animals (92%), such as raccoons, skunks, foxes, and bats. Programs to vaccinate domestic animals have reduced the number of rabies cases in dogs and cats, which has, in turn, decreased the risk to humans.

Humans usually acquire the rabies virus when they are bitten or scratched by animals with rabies. With the number of endemic areas increasing among wildlife, the risk of human exposure to rabies increases because of the increased likelihood of encountering a wild animal with rabies or a domestic animal that has contracted rabies from wildlife. Humans infected with the rabies virus experience a brief prodromal period of pain at the exposure site and have vague flulike symptoms. Mental status changes, such as anxiety, irritability, and depression, can also occur. After the prodromal period, patients suffer additional CNS changes, including hallucinations, paralysis, excessive salivation, hydrophobia, bouts of terror, seizures, respiratory and cardiac abnormalities, and hypertension. These symptoms are followed ultimately by

coma and death. In 2004, a Texas hospital encountered five cases of rabies. This occurrence was a result of transplanting organ and tissues from a person who was later discovered to have been a victim of a bat bite into four patients, all of whom subsequently died because of the disease. Rabies virus is not considered a bloodborne pathogen; therefore it is likely that the spread was caused by infected nerve tissue that came with the new organs.

Laboratory diagnosis of rabies involves determining whether an animal that has bitten a human has rabies. The animal is killed, and its head is removed and sent to a reference laboratory. The fastest and most sensitive method of identifying rabies virus in a specimen is by using a direct IF technique. Impression smears should be made from various areas of the brain, primarily the hippocampus, pons, cerebellum, and medulla oblongata. In living patients suspected of having rabies, skin biopsy, especially at the hairline at the back of the neck, and an impression of the cornea may be performed. The presence of rabies virus in these specimens is diagnostic, but its absence merely means that no virus is present in those specific specimens, not that the patient does not have rabies. EIAs are currently the most sensitive assays to use for serologic tests. Rabies virus can be grown in suckling or young adult mice, murine neuroblastoma, or related cell lines.

Rabies cannot be successfully treated once symptoms appear. However, postexposure prophylaxis is 100% effective in preventing the disease if the bite victim is treated immediately after exposure. Postexposure prophylaxis includes vigorously cleansing the wound site, providing human anti-rabies immunoglobulin, and administering a three-injection series of the rabies vaccine. Each year, more than 15 million people worldwide receive postexposure preventive treatment. This is estimated to prevent 327,000 rabies deaths annually.

Two approved human vaccine preparations are available in the United States: IMOVAX (Sanofi Pasteur Biologics, Canton, MA) and RabAvert (GlaxoSmithKline, Philadelphia, PA). The vaccine can be given to persons who may have been exposed to rabies, such as veterinarians, laboratory personnel, people who explore caves, and those visiting high-risk countries for longer than 30 days. Only one unvaccinated person with rabies has ever survived. A female teenager in Wisconsin developed rabies about 1 month after being bitten by a rabid bat. She was put into a coma and treated with several antiviral compounds. However, the reason for her survival is still not completely understood. Her survival resulted in a new method of rabies treatment called the Milwaukee Protocol.

Togaviridae

The family Togaviridae contains the genera *Alphavirus*, *Rubivirus*, and *Arterivirus*. No member of the genus *Arterivirus* is known to infect humans. Many of the viruses in the genus *Alphavirus* are mosquito-borne and cause encephalitis. Eastern equine encephalitis (EEE), which causes disease in horses and humans, occurs primarily in the eastern half of the United States. From 2010 to 2020, 120 human cases were reported, with a mortality rate of about 45%. Infections can cause a range of effects, from mild flulike symptoms to encephalitis. Of those who survive, almost 50% suffer permanent CNS

damage. Birds are the natural reservoirs of the virus, which is spread to humans and horses via bites of mosquitoes. Because horses and humans are dead-end hosts, EEE in horses can be a predictor of human EEE cases.

The western equine encephalitis (WEE) virus also causes disease in humans and horses. WEE virus causes a milder disease compared with EEE virus, and patients develop an asymptomatic or mild infection consisting of fever, headache, nausea, and mental status changes. Of young children and infants who survive, 5% to 30% will suffer permanent CNS damage. Mortality is about 3%. Since 1964, 639 cases were reported in the United States, but none have been reported since 1994.

Venezuelan equine encephalitis (VEE) has caused large outbreaks of human and equine encephalitis in the Americas. Outbreaks of epizootic strains have affected up to 75,000 people during a single epidemic. Death is much less common in patients with VEE than in patients with WEE or EEE. Between 4% and 14% of infected individuals will develop neurologic disease. Infected adults often develop a flulike illness, whereas encephalitis is more commonly seen in children with VEE.

Rubella virus is an enveloped virus belonging to the genus *Rubivirus*. It causes the disease rubella, or German measles, a mild febrile illness accompanied by an erythematous, maculopapular, discrete rash with postauricular and suboccipital lymphadenopathy. Like measles, rubella occurs most frequently in winter and spring. The diseases are so similar that as many as 50% of suspected measles cases are diagnosed as rubella. The rubella virus is transmitted via droplets. The virus is present in nasopharyngeal secretions or any secretion of infected infants, who shed the virus in large amounts for long periods. A rash starts on the face and spreads to the trunk and limbs. No rash appears on the palms and soles. About 50% of those infected with rubella virus are asymptomatic. Transient polyarthralgia and polyarthritis can occur in children and are common in adults.

Rubella would be of little concern if it did not cross the placenta and spread to the fetus, which results in congenital rubella syndrome. The syndrome can cause effects ranging from birth of a normal infant to birth of a severely impaired infant, fetal death, or spontaneous abortion. Because the

rubella virus halts or slows cell growth, the impact on the embryo is worse when the infection develops in the earliest stages of pregnancy.

An effective attenuated vaccine is available and should be administered to all children and to young women before they become sexually active. In 2004, the CDC declared the United States rubella free, meaning an absence of continuous disease transmission for 12 months or more. Currently, fewer than 10 cases are reported annually, and since 2012, all cases were acquired outside the country. Before the vaccination program began in 1969, about 12.5 million people contracted rubella annually.

It is important to collect specimens (e.g., throat swabs) the day the rash appears. Direct examination of specimens with RT-PCR has been attempted. However, not all are significantly sensitive to be used on clinical specimens, and no protocol for detecting viral RNA has been established. Several molecular tests are being evaluated. Isolation procedures are difficult because of the lack of a cell line that exhibits cytopathic effect. Infected cells can be detected by RT-PCR. Serologic procedures are effective because any rubella antibody is presumed to be protective. The most sensitive serologic assays are the solid-phase and passive hemagglutination tests. Latex agglutination and antigen-coated RBC tests are useful but less sensitive.

Hepatitis viruses

The hepatitis viruses are grouped together, not because of their structural or genetic similarities but because they share the same tissue tropism—the liver. Before the 1970s, patients with hepatitis were classified as having infectious hepatitis or serum hepatitis. Infectious hepatitis was transmitted from person to person via the fecal-oral route, and serum hepatitis resulted from transfusion of or exposure to infected blood and blood products. During the past several years eight different human hepatitis viruses have been recognized. The most clinically significant are HAV, HBV, HCV, and hepatitis D virus (HDV) (see [Table 29.7](#)). Four additional viruses have been described: hepatitis E virus (HEV), hepatitis G virus (HGV), SEN virus, and transfusion-transmitted virus (TTV).

Table 29.7 Clinical and epidemiologic differences among HAV, HBV, HCV, and HDV

Clinical Features	Hepatitis A (HAV)	Hepatitis B (HBV)	Hepatitis C (HCV)	Hepatitis D (HDV)
Incubation (days)	15–45	30–120	40–50	21–90
Type of onset	Acute	Insidious	Insidious	Usually acute
Mode of transmission				
Fecal-oral	Usual	Not likely	Not likely	Not likely
Parenteral	Increasing	Usual	Likely	Usual
Other	Foodborne, waterborne	Intimate contact, trans-mucosal transfer	Vertical transmissionIntranasal cocaine use	Intimate contact, less efficient than for hepatitis B virus
Sequelae				
Carrier	No	Yes	Yes	Yes
Chronic hepatitis	No	Yes	Yes	Yes
Mortality (%)	0.1–0.2	0.5–2.0	0.2–0.3	30 (chronic form)

HAV and HEV are transmitted via the fecal-oral route; HBV, HCV, HDV, HGV, SEN virus, and TTV are transmitted via contact with infected blood and blood products. HBV, TTV, and SEN virus have DNA genomes, whereas the others have an RNA genome.

Despite the biological and morphologic differences among the hepatitis viruses, many of the clinical symptoms caused by them are similar. Therefore differentiation based on clinical findings should not be relied on for diagnosis. The most common signs and symptoms are fatigue, headache, anorexia, nausea, vomiting, abdominal pain (right upper quadrant or diffuse), jaundice, and dark-colored urine.

Hepatitis A virus

HAV is a small, icosahedral, naked ssRNA virus, the sole member of the genus *Hepatovirus* in the family Picornaviridae. HAV infects people of all ages. In the United States, reported cases declined from the 1990s, when the annual average was about 25,000, to 2014, when 1239 cases were reported. In 2015, cases began increasing and reached 18,846 in 2019. The 30- to 39-year age group had the highest rate of infection, 14.5/100,000 population. In 2022, the CDC reported an outbreak of HAV infection linked to fresh organic strawberries. As of June 2022, 18 cases were confirmed. The WHO estimates that 1.5 million clinical cases of HAV infection occur each year.

HAV is almost always transmitted via the fecal-oral route and is usually acquired through close personal contact or via contaminated food. The risk factors for HAV infection include sexual or household contact with an infected person, daycare contacts, foodborne or waterborne outbreaks, IV drug use, and international travel. However, almost 50% of the cases in the United States have no established risk factor. The virus is shed in large amounts in feces during the incubation period and early prodromal stage, and food and water contamination

can result. The incubation period for HAV infection is approximately 1 month. After infection, individuals experience a transient viremia, after which the virus reaches the liver and replicates in hepatocytes. The virus passes into the intestine, and viral shedding begins and can persist for months.

Infections in more than 90% of children younger than 5 years of age tend to be asymptomatic. In adults, symptoms can range from mild to severe prolonged hepatitis. The onset is abrupt, and patients experience fever, chills, fatigue, malaise, aches, pains, and, in some cases, jaundice. The infection is self-limiting, with convalescence possibly lasting weeks. Complete recovery can take months. HAV infection has a low mortality rate and no persistence and does not cause chronic liver damage.

The most common method for laboratory diagnosis of HAV infection is to demonstrate IgM to HAV (Fig. 29.25). Isolation of HAV is not practical because it is difficult to grow in culture and tends to mutate drastically. Some reference laboratories offer in-house RT-PCR assays that can detect HAV infection before liver enzymes are elevated. Studies comparing antibody detection with RT-PCR have shown that HAV RNA can be detected much earlier after infection. Vaccination of children has the potential to reduce the incidence of HAV infection. Other vaccination target groups include people who travel to countries with endemic HAV, MSM, drug abusers, and patients with chronic liver disease. Persons who have not been vaccinated and have been exposed to HAV can receive immunoglobulin therapy, which is 80% to 90% effective in preventing infection when administered soon after exposure. Immunoglobulin therapy can also be used as preexposure prophylaxis.

Hepatitis B virus

HBV is an enveloped, partially dsDNA virus that belongs to the family Hepadnaviridae. The virus contains the hepatitis B surface antigen (HBsAg), which circulates in the bloodstream

Fig. 29.25 Serologic evaluation of hepatitis A virus (HAV) infection showing the increase and decrease of detectable antibodies. *IgG*, Immunoglobulin G; *IgM*, immunoglobulin M; *LFT*, liver function test.

as 22-nm particles. The whole virus has a total diameter of about 45 nm. The virion also contains a hepatitis B core antigen (HBcAg) and hepatitis B envelope antigen (HBeAg). Eight genotypes of HBV have been identified (A to H), and several studies have shown a difference in clinical outcome based on the genotype.

Almost one half the world's population lives in areas with endemic HBV, and more than 8% of the population is positive for HBsAg. According to the WHO, about 296 million people worldwide are infected with HBV. In the United States, the prevalence rate among adults decreased from 5.7/100,000 in 1999 to 1.0 in 2019. The incidence of acute HBV infection is estimated to be about 20,700 cases annually.

HBV is primarily a bloodborne pathogen. Infected individuals can have as many as 1 million infectious particles per milliliter of blood. Lower concentrations of virus appear in semen, vaginal fluid, and saliva. Many other body fluids (e.g., tears, urine, sweat, breast milk) contain HBsAg but do not seem to be infective. The main modes of transmission are through sexual, perinatal, and parenteral routes. In the United States, heterosexual and male homosexual contacts are the most common routes of transmission. High-risk groups include IV drug abusers, MSM, individuals from endemic areas, persons with household or sexual contacts with HBV carriers, health care personnel, people with tattoos or body piercings, and infants born to HBV-positive mothers. Almost one third of the patients who become infected, however, have no known risk factor.

The human cost of infection is high. An estimated 820,000 deaths per year worldwide are related to HBV infection. Once HBV enters the host, it travels from the bloodstream to the liver and infects the hepatocytes. Cytotoxic T cells then attack the HBV-infected hepatocytes. The incubation period for HBV infection ranges from 2 to 6 months, with an insidious onset that includes symptoms of fever, anorexia, and hepatic tenderness. Jaundice occurs in only about 10% of children who are younger than 5 years of age and is much more common in older children and adults (32% to 54%).

As the immune response is activated, the virus is slowly cleared from the system, and most patients become noninfectious. In adults, about 50% of infections are asymptomatic; 20% to 30% of patients exhibit clinical jaundice but have a benign resolution of the infection. Therefore about 80% of infections do not cause serious sequelae. The risk for chronic infection is inversely proportional to the age at the time of infection, with approximately 90% of infants and only 3% of adults developing chronic infection. Individuals with chronic infection have a higher risk of liver disease, such as cirrhosis or hepatic carcinoma. A safe and effective recombinant vaccine is available for preventing HBV infection. The U.S. Advisory Committee on Immunization Practices recommends that the series begins at birth and be completed by 6 to 18 months.

Diagnosis of HBV infection is based on clinical presentation and demonstration of specific serologic markers for HBV (Box 29.4). Serum aminotransferase levels also increase in infected patients. The presence of HBsAg in a patient's serum indicates that the patient has an active HBV infection, is a long-term carrier, or is in an incubation period. IgM anti-HBc appears early in the course of the disease and indicates an acute infection. In patients in whom HBsAg is not detected and anti-HBs has not yet appeared, detection of IgM anti-HBc confirms the diagnosis of acute HBV infection. The period

BOX 29.4 Serologic markers for the diagnosis of hepatitis B virus infection

- HBsAg—hepatitis B surface antigen, the envelope protein consisting of three polypeptides
- Anti-HBs—antibody to hepatitis B surface antigen
- Anti-HBc—antibody to hepatitis B core antigen
- HBeAg—antigen associated with the nucleocapsid, also found as soluble protein in serum
- Anti-HBe—antibody to hepatitis B envelope antigen

between the inability to detect HBsAg and the detection of anti-HBs antibodies is referred to as the *core window*. The detection of anti-HBs antibodies in serum indicates convalescence or immune status.

When the infection resolves, IgG anti-HBc and anti-HBs antibodies become detectable in the patient's serum. The presence of HBsAg after 6 months of acute infection is a strong indication that the patient is a long-term carrier; the appearance of HBeAg in this case is indicative of a chronic infection and high infectivity. Table 29.8 shows the interpretation of HBV serologic markers. Fig. 29.26 depicts the increase and decrease in the levels of detectable serologic markers during acute HBV infection and resolution and presentation of chronic HBV infection. Several molecular assays are available that detect viral DNA and provide a short TAT and very sensitive detection.

Hepatitis D virus

HDV, also known as the *delta hepatitis virus*, is a defective 1.7-kb ssRNA virus that requires HBV for replication. HDV requires the HBV HBsAg for its envelope. HDV is the sole member of the genus *Deltavirus*, and the genus is not currently assigned to a family. HDV is transmitted primarily via parenteral routes, although transmission through mucosal contact has been implicated in epidemics in endemic areas. At-risk groups in the United States are primarily IV drug users, although limited numbers of MSM in certain parts of the country are also at risk. Because of overlap in the clinical presentation, presumed low incidence of infection, and lack of an effective surveillance mechanism, current epidemiologic data on HDV are minimal.

HDV infection is rare but usually severe and results in acute disease, with a fatality rate of 5%, or chronic symptoms progressing to cirrhosis in two thirds of those infected. The infection can occur in one of two clinical forms: co-infection or superinfection. In co-infection, the patient is simultaneously infected by HBV and HDV. In superinfection, HDV infection develops in a patient with chronic HBV infection. Patients with superinfection have a more severe acute infection and have a higher risk of fulminant hepatitis compared with patients with co-infection. Long-term carriers of HBV who become superinfected with HDV also develop chronic HDV infection, which increases their chance of developing cirrhosis.

Diagnosis of HDV infection requires serologic testing for specific HDV antibody. Commercial tests are available for IgG anti-HDV antibody. Reference laboratories may offer IgM anti-HDV antibody testing and PCR assay for HDV. Table 29.9 presents the interpretation of HDV serologic

markers; Fig. 29.27 depicts serologic presentations of HDV co-infection and superinfection. Detection of HDV RNA is done with RT-PCR, and diagnosis using this method is becoming more common from liver tissue.

Hepatitis C virus

After methods for diagnosing HAV and HBV became available, it was apparent that these two viruses were not

responsible for all hepatitis cases, especially those related to blood transfusions. The resulting disease was termed *non-A, non-B (NANB) hepatitis*. The diagnosis of NANB hepatitis was primarily one of exclusion. In 1974, without any direct evidence, scientists predicted that a type C hepatitis virus must exist. Then, 15 years later, with the aid of molecular and cloning techniques, the genomic sequence of HCV was determined before the virus was ever seen with an electron microscope.

HCV is an ssRNA virus in the genus *Hepacivirus*, family *Flaviviridae*; it accounts for about 90% of all previous cases of NANB hepatitis. There has been a gradual increase in the annual incidence of acute HCV infections in the United States since 2012. In 2019, 4136 cases were reported, but the CDC estimates that 57,500 acute cases occurred. Worldwide, as many as 1.5 million new cases may develop each year, and an estimated 58 million people have chronic HCV. Although perinatal and sexual transmission of infection occur and parenteral transmission has been identified as a major route for infection, HCV antibodies have been detected in patients in

whom the routes of transmission are poorly understood or who have no evidence of identifiable risk factors.

Symptoms can be subtle and may take time to become apparent. About 50% of HCV-positive patients become long-term carriers, and about 20% to 30% of patients with chronic infections develop cirrhosis. Cirrhosis is a major risk factor for hepatocellular carcinoma. In 2019, over 100,000 new chronic HCV infections were recorded in the United States. It is estimated that the number of U.S. citizens living with chronic HCV is 2.4 million, but it might be as many as 4.7 million. Among the three hepatitis viruses—HAV, HBV, and HCV—HCV has the highest mortality rate.

Gene amplification tests prove that HCV RNA appears in newly infected patients in as little as 2 weeks. However, most infections are detected by serologic testing. HCV is less immunogenic than HBV. Antibodies to HCV appear in about 6 weeks in 80% of patients and within 12 weeks in 90% of patients. HCV infection does not produce persistent, life-long levels of antibody; rather, persistence of anti-HCV antibody is linked to the presence of replicating HCV.

EIAs that detect serum antibodies to HCV proteins are available as screening tests; however, they can have a low sensitivity. Second-generation immunoblot assays use recombinant and/or synthetic proteins to detect anti-HCV antibodies. Currently, third-generation tests are more sensitive and accurate and are commonly used. These assays also employ recombinant proteins but have an improved version of NS3 and have added NS5. Confirmation currently relies on nucleic acid amplification testing. Figure 29.28 depicts the immunologic profile of HCV infection.

Patients with chronic HCV infection were previously treated with interferon, with or without ribavirin. First approved in 2011, direct-acting antiviral (DAA) therapy has proven highly effective in curing HCV infection. DAAs are molecules that target specific nonstructural proteins of the virus, which results in disruption of viral replication and infection. There are four classes of DAAs defined by their mechanism of action and therapeutic targets.

Hepatitis E virus

HEV is a small (32 to 34 nm), naked, ssRNA virus classified in the genus *Hepevirus*, family *Hepeviridae*. HEV is transmitted via the fecal-oral route, particularly through contaminated drinking water. HEV has been identified as the cause of epidemics of enterically transmitted hepatitis in developing countries in Asia, Africa, and Central America. Although the virus has not been associated with outbreaks in the United States, it has been linked to sporadic cases in travelers returning from endemic areas.

HEV causes an acute, self-limiting disease with clinical symptoms like those of HAV. The incubation period is 2 to 9 weeks. Signs and symptoms of HEV infection include fever, malaise, nausea, vomiting, jaundice, and dark-colored urine. No specific antiviral therapy is available; patients receive supportive therapy. Viral shedding in feces has been shown to persist for several weeks. The mortality rate is 1% to 3% overall, with a higher likelihood of death in women who are pregnant (15% to 25%). Epidemics affect primarily young to middle-age adults. An ELISA test is available to detect IgG and IgM anti-HEV antibodies, although HEV testing is not currently performed in diagnostic laboratories in the United States.

Other hepatitis viruses

Evidence for HGV was derived originally from a patient with NANB hepatitis. This RNA virus, now known as GB virus type C (GBV-C), is a member of the family *Flaviviridae*. GBV-C viremia has been demonstrated worldwide in 0.6% to 14% of blood donors, depending on the geographic location. However, infection does not seem to be common in the United States. The clinical significance of the virus is still under investigation. Experimental RT-PCR tests can be performed to detect the virus, but routine testing is not yet recommended.

The most recently identified hepatitis viruses are SEN virus and TTV. SEN virus has a circular DNA genome. It is

Fig. 29.28 Serologic evaluation of hepatitis C virus (HCV) infection showing the persistence of detectable antibodies, indicating the presence of replicating HCV. LFT, Liver function test.

bloodborne, and although originally suspected to be a cause of hepatitis, it has not been definitively linked to any human disease. Transmission appears to be linked to blood transfusion. About 30% of patients with HIV infection have antibodies to the SEN virus. TTV was first identified in the serum of a Japanese patient in 1997. It is an ssDNA virus related to animal circoviruses. The role of TTV in human disease is unknown but may be associated with some cases of post-transfusion hepatitis.

Prions

Prions are not viruses but are proteinaceous infectious particles that cause a group of diseases in mammals called *transmissible spongiform encephalopathies* (TSEs). The name *prion* (from the words **protein** and **infection**) was coined by Stanley B. Prusiner in 1982. Examples of TSEs include kuru and Creutzfeldt-Jakob disease (CJD) in humans, scrapie in sheep, bovine spongiform encephalopathy (BSE) in cattle, and chronic wasting disease in deer and elk. BSE, also referred to as *mad cow disease*, was responsible for the loss of hundreds of thousands of cattle in the United Kingdom, most notably during the 1980s.

An increase in a variant form of CJD (vCJD) in the United Kingdom was noted at about the same time as the surge of BSE. It appears that the agent of scrapie crossed species and infected cows and that it is the causative agent in BSE-infected humans, causing vCJD. Between 1993 and 2018, 26 cases of BSE were discovered in North America: 6 cases in the United States and 20 in Canada. TSEs are known to be acquired via ingestion, although some prions may also enter the body by other routes. Sheep offal used in cattle feed was the likely cause of the prion moving from sheep to cattle.

TSEs are characterized by progressive, relentless degeneration of the CNS, which is ultimately fatal. Typical histopathology is neuronal vacuolation and eventual loss of neurons, accompanied by proliferation and hypertrophy of fibrous astrocytes. The prion protein (PrP) found in animals with TSE is often referred to as PrP^{Sc}, named after the prion found in sheep with scrapie. Animals, including humans, have a similar but normal protein found on cells of the CNS, referred to as PrP^C. Ingested PrP^{Sc} is absorbed into the bloodstream and makes its way into the CNS. PrP^{Sc} converts PrP^C into PrP^{Sc}, which is released by neuronal cells. PrP^{Sc} accumulates in the CNS, producing amyloid plaques and the characteristic histopathology.

The diagnosis of TSE is often based on clinical findings. Routine analysis of CSF is nonrevealing. Many patients with CJD will have 14-3-3 proteins in CSF; however, these proteins are not specific for CJD. The presence of these proteins in CSF is a marker for rapid neuronal cell death, present not only in CJD but also in encephalitis and conditions with CNS hemorrhaging. Histopathology staining and PrP^{Sc} immunostaining remain the most specific diagnostic methods. Other detection methods include antigen detection, serologic testing, and nucleic acid sequencing for inheritable forms. Recent findings have suggested the excretion of TSEs in urine.

The risk of infection to laboratory personnel is low, but material suspected of containing these agents must be handled carefully. Prions are extremely resistant to inactivation; even 2 hours in a steam autoclave might not inactivate all

prions in a specimen. Exposure to household bleach with more than 20,000 parts per million available chlorine or 1 M sodium hydroxide is recommended. It is not recommended to test any specimens from a suspected case of prion disease until it is ruled out because instrumentation cannot be sufficiently decontaminated, and it presents a risk of infection to staff.

Treatment and management of viral infections

Viruses have evolved to replicate inside host cells. Since the virus uses host machinery to replicate, most drugs targeting viruses have the potential to affect the host cell as well. Viruses with very high mortality rates (e.g., Ebola virus) are often eradicated equally rapidly as the survival of virus relies on effective transmission to new hosts. Therefore most pathogenic viruses eventually mutate to milder infections and become more contagious. This is the trend being observed in the ongoing COVID-19 pandemic. Most mild viral illnesses are not treated; instead, supportive care is provided for the viral cycle to be completed, and quarantine of infected individuals is recommended to break the transmission cycle.

Antiviral therapy

Some viral infections are treatable, especially if the laboratory can rapidly identify the pathogen. Antiviral compounds must target an essential viral replicative mechanism without destroying or damaging uninfected host cells. Several antiviral agents resemble nucleosides used in viral replication. The viruses insert these nucleoside analogues into their own nucleic acid, resulting in disruption of viral replication. Other antivirals are non-NRTIs, which also disrupt viral replication. Phosphonoformic acid (foscarnet) is an analogue of pyrophosphate that acts directly as a DNA polymerase inhibitor. Other antiviral compounds inhibit viral replication by targeting key viral proteins (e.g., protease inhibitors). Some commonly used antiviral agents are given in [Table 29.10](#). A number of antiviral drugs have been developed, and several are in clinical trials for the treatment of COVID-19.

Just as antibacterial agent use increases the risk of drug resistance in bacteria, the use of antiviral agents can result in viruses that become resistant to therapy. As more antiviral agents become available, antiviral susceptibility testing will become increasingly important. For example, foscarnet is currently being used to treat infections caused by HSV strains resistant to acyclovir and to treat CMV strains resistant to ganciclovir.

Vaccines

Development of vaccines for highly contagious viruses is a top priority in the management of clinically relevant viral infections. A vaccine is composed of a highly weakened attenuated virus or virus component that can trigger an immune response. When the body encounters the actual infection, the host will mount a heightened (anamnestic) immune response, ultimately leading to clearance of the infectious agent. It is important to note that vaccines prevent disease

Table 29.10 Examples of antiviral compounds

Antiviral	Inhibits	Active against
Acyclovir	DNA polymerase	HSV, VZV
Cidofovir	DNA polymerase	CMV (retinitis)
Famciclovir	DNA polymerase	HSV-2
Ganciclovir	DNA polymerase	CMV (retinitis)
Valacyclovir	DNA polymerase	HSV-2
Idoxuridine, trifluridine	DNA synthesis (DNA base analogue)	HSV (keratitis)
Amantadine, rimantadine	Uncoating	Influenza A (treatment and prophylaxis)
Interferon- α	Viral replication (multiple mechanisms)	HPV (genital warts); chronic HCV, Kaposi sarcoma
Ribavirin	Viral replication (multiple mechanisms)	RSV, CCHF
AZT or ZDV	Reverse transcriptase	HIV
ddI	Reverse transcriptase	HIV
ABC	Reverse transcriptase	HIV
3TC	Reverse transcriptase	HIV
d4T	Reverse transcriptase	HIV
ddC	Reverse transcriptase	HIV
FTC	Reverse transcriptase	HIV
TDF	Reverse transcriptase	HIV
Indinavir	Proteases	HIV
Nelfinavir, ritonavir	Proteases	HIV, CoV-2
Saquinavir	Proteases	HIV
Lamivudine		Chronic HBV
Adefovir		Chronic HBV
Remdesivir	Adenosine analog	CoV-2

ABC, Abacavir sulfate; AZT, azidothymidine; d4T, stavudine; CCHF, Crimean-Congo hemorrhagic fever; CMV, cytomegalovirus; CoV-2, coronavirus 2; ddC, zalcitabine; ddI, didanosine; FTC, emtricitabine; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; 3TC, lamivudine; TDF, tenofovir; VZV, varicella-zoster virus; ZDV, zidovudine.

successful vaccines like smallpox vaccine and polio vaccine were tremendously successful, leading to eradication or near eradication of these viral diseases worldwide. Most recently, three COVID-19 vaccines were developed, two of which (Moderna [Cambridge, MA] and Pfizer [New York, NY]-BioNT [Germany]) used mRNA coding for a surface protein of SARS-CoV-2. The third, from Johnson and Johnson (New Brunswick, NJ), used an attenuated virus. These vaccines have been instrumental in curbing the spread and mortality of COVID-19. Global efforts to invest in research and development of effective vaccines as well as increasing awareness to the public about the safety and efficacy of vaccinations is a key step to prevent future pandemics.

POINTS TO REMEMBER

- Viruses have been responsible for several pandemics including influenza viruses and coronaviruses.
- Clinical virology services can consist of rapid antigen detection, NAATs, antibody detection, or cell cultures.
- Clinically significant viruses can be isolated from patients with signs and symptoms commonly thought to be associated with bacterial infections, including pneumonia, GI disorders, cutaneous lesions, sexually transmitted infections, and sepsis.
- Members of the family Herpesviridae produce life-long, latent infections.
- Most cases of cervical cancer are linked to HPV, the causative agent of genital warts.
- Some viruses mutate rapidly, resulting in new strains, which can be challenging to contain or treat.
- Retroviruses (e.g., HIV) replicate with reverse transcriptase, which uses viral RNA as a template to make a complementary DNA strand.
- Arboviruses are those viruses transmitted by the bite of arthropods, such as mosquitoes.
- Many emerging infections are caused by zoonotic viral agents that are unexpectedly transplanted into a susceptible human population.
- The hepatitis viruses are a diverse collection of viruses grouped together because they all infect primarily the liver. Laboratory diagnosis is based on serologic markers.
- Antiviral compounds can treat numerous viral infections, but resistance has been seen.
- Vaccines against viruses is an effective way to manage viral infections and severity.

LEARNING ASSESSMENT QUESTIONS

1. Which of the following serologic markers should be positive following administration of the HBV vaccine?
 - a. HBeAg
 - b. HBcAg
 - c. Anti-HBs
 - d. Anti-HBc
2. Which of the following conditions is most often associated with rotavirus?
 - a. Infant diarrhea
 - b. Paralysis in children

but not infection. Those infected after vaccination are usually asymptomatic, or have a milder form of disease, and eliminate the infectious agent quickly. They are much less likely to transmit the agent to other hosts. Once a significant percent of the population develops immunity, either by vaccination or surviving the disease, the infection rate becomes very low. This concept is referred to as *herd immunity*.

Unfortunately, due to the high rate of mutations, effective vaccines cannot be developed for all viruses. A number of

- c. Infant respiratory infections
- d. Infectious mononucleosis-like symptoms in young adults
3. Which virus causes fifth disease?
 - a. Molluscum contagiosum
 - b. Parvovirus B19
 - c. Measles virus
 - d. Varicella-zoster virus
4. During the “core window” of acute hepatitis B virus infection, what is the primary marker for diagnosis?
 - a. HBsAg
 - b. HBeAg
 - c. Anti-HBs
 - d. Anti-HBc
5. Reactivation of the virus causing chickenpox results in which condition?
 - a. Shingles
 - b. Infectious mononucleosis
 - c. Dengue fever
 - d. Polio
6. The presence of Kaposi sarcoma in a young adult is suggestive of which illness?
 - a. West Nile fever
 - b. Ebola hemorrhagic fever
 - c. Acquired immunodeficiency syndrome
 - d. Coronavirus disease
7. A patient suspected of having hepatitis has a positive anti-hepatitis C virus (HCV) antibody test. Which of the following should be done next?
 - a. Report the patient as HCV positive.
 - b. Perform an anti-HBs test to rule out a false positive
 - c. Request a second blood sample to repeat the test.
 - d. Confirm the result with a nucleic acid amplification test for HCV.
8. What is the greatest risk for developing dengue hemorrhagic fever?
 - a. History of dengue fever with a different serotype
 - b. Older than 50 years of age
 - c. Diabetes
 - d. Obesity
9. What is the most common complication of West Nile fever?
 - a. Pneumonia
 - b. Neuroinvasive disease
 - c. Chronic hepatitis
 - d. Osteomyelitis
10. Which of the following specimens is best to recover cytomegalovirus?
 - a. Nasopharyngeal swabs
 - b. Bronchial wash
 - c. Buffy coat
 - d. Saliva
11. Which opportunistic infections or conditions are used as indicators of acquired immunodeficiency syndrome (AIDS)?
12. Which immunologic markers are used to diagnose human immunodeficiency virus (HIV) infection?
13. What disease does Epstein-Barr virus (EBV) produce? What complications can result from EBV infections?
14. How is acute hepatitis B virus (HBV) infection differentiated from chronic infection? Which markers indicate resolution of the infection?

15. What are the differences between classic dengue fever and dengue hemorrhagic fever?
16. What are the methods commonly used to diagnosis rabies?
17. Which types of infections are caused by human papilloma-virus (HPV)?
18. Which viruses have the potential for latency?
19. Why are vaccines for influenza not always effective?
20. What type of vaccines showed highest success against SARS-CoV-2 virus?

Agents of bioterror and forensic microbiology

Christopher J. Woolverton and Donald C. Lehman

CHAPTER OUTLINE

Bioterrorism readiness and the clinical laboratory, 754

Laboratory response network, 756

General characteristics of biological threat agents, 757

Biological risk management, 758

Biosafety, 759

Biosafety levels, 759

Agents of bioterror, 760

Bacillus anthracis, 760

Burkholderia species, 762

Clostridium botulinum neurotoxin, 764

Ebola virus and Marburg virus, 764

Francisella tularensis, 766

Variola virus, 767

Yersinia pestis, 769

Other biological agents and toxins, 771

Pandemic preparedness and bioterrorism readiness, 771

Concluding thoughts, 772

Forensic microbiology, 772

Bibliography, 774

9. Describe the evolution of the use of biological agents throughout history.
10. Differentiate the roles of the three levels of Laboratory Response Network (LRN) laboratories: sentinel, reference, and national.
11. Describe the roles of organizations that offer support for the preparation and investigation of potential bioterror events.
12. Compare the pathogenesis and the mode of transmission of each bioterror agent.
13. Identify specific virulence factors unique to each tier 1 bioterror agent.
14. Associate the clinical manifestations of infection with the bioterror agents listed in this chapter.
15. Identify the necessary characteristic growth patterns, Gram stain morphology, and biochemical test results to rule in or rule out *Bacillus anthracis*, *Yersinia pestis*, and *Francisella tularensis*.
16. Based on a health care provider's suspicion, identify the ideal specimens to submit for testing and any special precautions or safety procedures to identify disease caused by variola virus, Ebola virus or Marburg virus, and *Clostridium botulinum* toxin.
17. Assess the impact of the anthrax bioterror incident on the modification or development of new policies and procedures dealing with bioterror threats.
18. Discuss the role of forensic microbiology.

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Identify the four levels of biosafety.
2. Describe the differences in special laboratory practices, safety equipment, and laboratory facilities.
3. Develop a biological risk assessment to recognize the adequate biosafety level (BSL) requirements for specific agents.
4. Summarize the features of an ideal bioterror agent.
5. Explain how CRISPR/CAS technology can be used to enhance the virulence of a bioterror agent.
6. Explain the differences among the categories of bioterror agents.
7. Compare the features of the four categories of BSL laboratories.
8. Compare the efficiency of the different routes used to disseminate bioterror agents.

KEY TERMS

Biocrime	Buboes
Biological agent	Bubonic plague
Biological risk assessment	Eschar
Biological warfare	Glanders
Biorisk	Inhalation anthrax
Biorisk management	Laboratory Response Network (LRN)
Biosafety	Mediastinitis
Biosafety levels (BSLs)	Melioidosis
Bioterrorism	Pneumonic plague
Biothreat	Risk group
Black Death	Select agents
Botulinum toxin	

Tier 1 agents
Tularemia
Vaccinia

Variola major
Variola minor

Case in point

On October 16, a 56-year-old African American man experienced fever, chills, headache, sore throat, and malaise. Symptoms progressed to difficulty in breathing, night sweats, nausea, and vomiting. He went to the hospital on October 19. At admission, he was afebrile, and his heart rate was 100 beats per minute. Physical examination found decreased breath sounds and rhonchi. His complete blood count was unremarkable, and serum chemistries and renal function tests were normal. Arterial blood gas did not show hypoxia. Chest radiography revealed a widened mediastinum, and computed tomography showed mediastinal edema. Specimens were collected for blood culture, and gram-positive bacilli presumptively identified as *Bacillus anthracis* grew within 11 hours. Therapy with ciprofloxacin, rifampin, and clindamycin was started. On October 21, the patient developed respiratory distress, and he was treated with diuretics and corticosteroids, and underwent thoracentesis. The patient eventually recovered.

Issues to consider

After reading the patient's case history, consider:

- Why *Bacillus anthracis* can be classified as both a BSL-2 and a BSL-3 agent
- Whether *B. anthracis* meets all features of an ideal bioterror agent
- What tests a sentinel laboratory should perform to rule out *B. anthracis*
- What clinical manifestations are indicative of a potential inhalational case of anthrax and whether a case, when identified, is always considered a bioterror event

Bioterrorism readiness and the clinical laboratory

The announcement of a severe acute respiratory syndrome (SARS)-like viral outbreak in Wuhan, China, at the end of 2019 triggered many people to wonder about its origin. The subsequent pandemic brought confusion, fear, and panic. As the sequence of events unfolded and infected individuals began to die, some wondered if the deadly virus had been intentionally released. Clinical laboratories worldwide scrambled to identify the pathogen. The initial disease pattern and epidemiology closely mirrored the plots of several apocalyptic tales of science fiction, leaving people to wonder if another bioterrorism attack had been perpetrated. The virus was named SARS-coronavirus-2 (CoV-2). Coronavirus disease 2019 (COVID-19) was labeled zoonotic; its origin is still unknown.

Bioterrorism is the intentional or threatened use of bacteria, viruses, fungi, or toxins from living organisms to produce death or disease in humans, animals, or plants. Implicit in this definition is the intention to cause civil and economic instability leading to fear, panic, and chaos. Bioterrorism can be classified as overt or covert. In overt bioterrorism, the impact will

be immediate, and there will be early recognition of the event, generally by emergency response personnel. Additionally, a group or society will often claim responsibility for such an event. Covert events pose more of a challenge. There may not be an initial announcement of an attack, early health care data may not differentiate it from a natural epidemic organism, and clinical microbiologists and health care providers will most likely be the first to suspect the attack. During covert bioterrorism, the recognition as well as the response could be delayed for days or weeks, allowing the disease to spread throughout a population.

To the terrorist, biological agents may seem easy to acquire and inexpensive to produce, and they can offer an alibi or escape as the agent multiplies in the infected person during its incubation period. To this end, a bioterror event may initially mirror a natural disease outbreak, but it would quickly overwhelm underprepared medical services. The clinical laboratory may not even have the correct reagents or media to support the correct diagnosis of the disease. We will learn later in the chapter how this has been addressed and how the clinical laboratorian can be prepared for a potential bioterrorism event.

Biological warfare is the deliberate use of bacteria, viruses, fungi, or toxins from living organisms to produce death or disease in humans, animals, or plants by a state-level organization to gain a military advantage and/or political gain. There are several incidents of biological warfare recognized throughout human history. In one of the first recorded cases, the Assyrian army of the sixth century B.C. poisoned the wells of their enemies with a rye ergot fungus. This specific fungus produced an alkaloid hallucinogen known as lysergic acid diethylamide (LSD). The hallucinogen distracted their enemies, thus granting easy victories to the Assyrians. In the fourth century B.C., Scythian army archers dipped their arrows in poisons made from blood, manure, and even decomposing bodies.

The most historically recognized biowarfare event occurred in the 14th century, when the Tartar army laid siege to the walled city of Caffa (modern-day Feodosiya, Ukraine). Unable to enter the fortified city, the army catapulted bodies of Mongol plague victims over the city wall to force the Genoese Christians out of their stronghold. History reveals that the Mongol corpses did not really transmit plague. Likely, the disease was started as rats crawled into the walled city, spreading the disease via bacteria-infected flea vectors (Fig. 30.1). The surviving Genoese, indeed, fled the city, but by way of the seaport side of the city, where ships carried them into the Black Sea. Unfortunately, it is believed that the rats and their infected fleas stowed aboard the ships, traveled with the Genoese to other European ports, and thus aided in the spread of the **Black Death** throughout Europe.

History also remembers the notorious misuse of microorganisms to control military outcomes during the French and Indian War (in the United States), when Sir Jeffery Amherst, the commander of British troops in North America, wrote a letter to Colonel Henry Bouquet suggesting the use of smallpox-contaminated materials to kill Native Americans sympathetic to the French. In 1763, Captain Simon Ecuyer, stationed at Fort Pitt, Pennsylvania, collected the blankets and a handkerchief used by a soldier at Fort Pitt who had recently died of smallpox. These contaminated items were presented to the Native American Delaware tribe, causing an outbreak and

Fig. 30.1 Scanning electron micrograph of a flea vector, which may transmit *Yersinia pestis* to humans via a blood meal ($\times 20,000$). (Courtesy Janice Haney Carr and Centers for Disease Control and Prevention, Atlanta, GA.)

nearly decimating the tribe so the British could claim a military victory against a French military post.

The “modern era” of biological weapons began during World War I, when Germany was believed to have used *Vibrio cholerae* and *Yersinia pestis* against humans and *B. anthracis* and *Burkholderia mallei* against animals. *B. mallei* was used to infect the horses and mules of Allied countries, thus preventing them from transporting supplies and equipment to the European war front. Despite a 1925 Geneva Protocol signed by 108 nations prohibiting the use of biological agents during war, several countries began biological warfare research programs in the 1920s that continued through World War II (1939 to 1945) and the Korean War (1950 to 1953). It was not until 1972 when a new document, summarizing the efforts of many nations and meant to supplement the 1925 Geneva Protocol, was presented for international ratification. Known as the Biological Weapons Convention, it set as its goal the banning of all offensive biological weapons. By 1975, 22 countries had ratified its *general-purpose criteria* that no signer of the agreement would develop, produce, stockpile, or otherwise acquire or retain (1) microbial or other biological agents or toxins that have no peaceful purpose and (2) weapons, equipment, or means of delivery designed to use such agents of toxins for hostile purposes or in armed conflict. With the hope that the Biological Weapons Convention would prevent state-sponsored biowarfare, the world continued to worry as isolated acts of **biocrime** (i.e., acts of bioterrorism committed by individuals and small groups) became more frequent in the late 20th century.

In 1984, the followers of Bhagwan Shree Rajneesh committed biocrimes when they used *Salmonella enterica* serovar Typhimurium as a weapon to help influence election results

in the Dalles, Oregon, community. By their covertly spraying liquid *Salmonella* cultures on restaurant salad bars, 751 persons developed culture-positive salmonellosis. Their plan to influence the election ultimately failed, but they raised serious concerns about how food and water could be used to deliver biological agents to unsuspecting victims.

Internationally, other incidents raised growing concerns that a bioweapons deployment program would succeed. The Japanese cult Aum Shinrikyo successfully deployed sarin gas in the subways of Tokyo in 1995, killing 12 and injuring almost 5000 people. The Aum also obtained and experimented with **botulinum toxin**, *B. anthracis*, and *Coxiella burnetii* and attempted to obtain Ebola virus (EBOV) from Zaire (now the Democratic Republic of the Congo). From 1990 to 1995, they tried several times to deploy botulinum toxin and anthrax spores in cities, all unsuccessfully.

One biocrime still remembered by many is the 2001 attacks on politicians and media celebrities with spores of *B. anthracis* sent through the U.S. mail. Envelopes laced with spores resulted in 22 cases of anthrax in five cities on the eastern seaboard, and dozens of buildings were contaminated. The U.S. Congress was temporarily closed, and the U.S. Postal Service was disrupted for years. Ultimately, five people died because of this attack and \$6 billion was spent in response costs. These and other events led the U.S. Department of Health and Human Services (DHHS) to enhance the **Laboratory Response Network (LRN)**, a national detection and mitigation program that could rapidly respond in the event of a bioterrorism crisis ([Box 30.1](#)).

Case check 30.1

Throughout the years, biological agents have been used for many purposes, such as to cause public panic, incapacitate individuals, and provide an advantage over one's enemy during military operations. The anthrax letters mailed in 2001 caused a great amount of panic and fear among the public. Many hospitals and laboratories were overwhelmed by individuals concerned that they had been exposed (often categorized as the “worried well”). The Case in Point is an example of the criminal use of *B. anthracis*.

BOX 30.1 Key indicators of a potential bioterror or biocrime event

- A disease entity that is unusual or that does not occur naturally in a given geographic area or combinations of unusual disease entities in the same patient populations
- Multiple disease entities in the same patients, indication that mixed agents might have been used in the event
- Above-normal rates of morbidity and mortality relative to the number of personnel at risk or within a population that inhabits the same area
- Data suggesting a massive point source outbreak
- Apparent aerosol route of infection
- Illness limited to localized or circumscribed geographic areas with filtered air supplies or closed ventilation systems
- Sentinel dead animals of multiple species
- Absence of a competent natural vector in the area of the outbreak (for a biological agent that is vector-borne in nature)

From U.S. Army Medical Research Institute for Infectious Diseases. (2000). *Biological warfare and terrorism medical issues and response satellite broadcast*. Ft. Detrick, MD: USAMRIID.

Laboratory response network

In an effort to increase responsiveness, standardize reagents and protocols, and create the ability nationwide to rapidly detect the deployment of biological weapons in the United States and its territories, infectious disease experts in academia, national public health experts, DHHS agency representatives, civilian and military intelligence experts, and law enforcement officials met in the late 1990s, in response to Presidential Decision Directive 39, to discuss the threat potential of infectious agents to civilian populations. One result was the reassessment of biological agents for their ability to cause harm in individuals and communities, should they be used as agents of bioterrorism. By law, the biological agents were placed into one of three categories—A, B, or C—for initial public health preparedness efforts. Revised legislation now categorizes select agents as *tier 1* or *non-tier 1* based on several criteria, including the degree of public health threat.

A second result of those meetings was the creation of the LRN in 1999, formed by the Centers for Disease Control and Prevention (CDC), the Association of Public Health Laboratories (APHL), the Federal Bureau of Investigation (FBI), and the U.S. Army. The stated goal of the LRN was to decentralize testing capabilities and link clinical laboratories and public health laboratories to advanced-capacity clinical, military, veterinary, agricultural, water, and food testing abilities. This integrated network of laboratories can respond rapidly to bioterrorism, emerging infectious diseases, chemical terrorism, or other public health emergencies. The LRN is a tiered response network (Fig. 30.2).

Thousands of laboratories in the United States perform diagnostic testing. Most modern hospital laboratories serve

in this “sentinel” capacity. By virtue of its daily contact with patient specimens, effective diagnostic testing, good laboratory practice, and clinical problem-solving skills, the local clinical (sentinel) laboratory is likely the first point of detection should victims of bioterrorism seek infectious disease diagnostics. Here, detection of locally atypical infectious organisms will initiate specific protocols to “recognize, rule out, and refer” specific microorganisms that might be used in bioterrorism acts. The American Society for Microbiology (ASM) publishes guidelines instructing sentinel laboratories how to conduct preliminary testing to recognize and rule out these “select agents” only when they are suspected from clinical diagnoses or initial test results.

When the select agent cannot be ruled out using the sentinel laboratory protocol, then the sentinel laboratory must cease identification procedures and send the isolate to the designated LRN reference laboratory for confirmatory identification. The sentinel laboratory completes a chain of custody form and prepares specimens for shipping. The CDC and the ASM also provide guidance on the proper procedures for packing and shipping isolates for transfer to an LRN reference laboratory. Importantly, sentinel clinical laboratories do not require registration with the Select Agent Program to conduct both tier 1 and non-tier 1 select agent *diagnostic* testing if the laboratory destroys any residual specimen and destroys or transfers the confirmed select agent within 7 days of identification. Reporting of all identified select agents is still required.

The LRN reference laboratory tier contains mostly state health department laboratories that have specific biosafety equipment, standardized reagents and controls, agent-specific protocols for the identification of **biothreat** agents, and highly trained staff. These reference laboratories can perform gene amplification and antigen detection. When practical, they also rely heavily on culture identification and characterization. Currently, the LRN has over 120 domestic laboratories, representing all 50 states, and several international laboratories.

The uppermost LRN tier represents the national centers that offer the greatest resources and responses to a biological terror event. They function in the development of new diagnostic tests, the design and testing of standardized protocols, and the definitive characterization of agents unclassified at lower levels. These laboratories are at the CDC, the U.S. Army Medical Research Institute of Infectious Diseases, the Naval Medical Research Center, and approximately a dozen strategically located U.S. facilities that have high-containment laboratories to handle the most dangerous agents (Fig. 30.3).

Fig. 30.2 Structure of the Laboratory Response Network.

Case check 30.2

The Case in Point demonstrates the quick and efficient reaction of sentinel facilities and member reference laboratories to organize and assess patients, samples, and tests in response to any potential threats. The laboratory that isolated *B. anthracis* in the Case in Point would be considered an LRN sentinel laboratory, which appropriately contacted the state public health laboratory (LRN reference laboratory) and referred the potential organism for confirmatory testing.

(Courtesy Dr. Scott Smith and Centers for Disease Control and Prevention, Atlanta, GA.)

General characteristics of biological threat agents

According to the *Code of Federal Regulations*, a **biological agent** is, by definition, any microorganism (including but not limited to bacteria, viruses, fungi, rickettsiae, or protozoa) or infectious substance, or any naturally occurring, bioengineered, or synthesized component of any such microorganism or infectious substance, capable of causing death, disease, or other biological malfunction in a human, animal, plant, or another living organism; deterioration of food, water, equipment, supplies, or material of any kind; or deleterious alteration of the environment. Some of these are recognized now as **select agents**, which are biological agents and toxins deemed by the DHHS to have the potential to pose a serious threat to public health and safety, and overlap select agents that have the potential to pose a severe threat to public health and safety, animal health, or animal products (Table 30.1). The Federal Select Agent Program oversees possession of any of these biological agents and toxins, requiring the registration of facilities that possess, use, or transfer them.

What makes biological agents so appealing to terrorist organizations? They are much less expensive to create than conventional weapons, and cultivating them may not require extensive training, expertise, or sophisticated equipment and supplies. The ideal biological agent would have high attack and fatality rates and have a very short interval between the onset of illness and death, making an accurate

and timely diagnosis very difficult. There would be limited civilian immunity and no available antimicrobial therapy, and it would be highly communicable. Finally, such an organism would be easy to produce and disseminate. Fortunately, of the known biological agents, none meet all these criteria. Thus, sooner or later, terrorist organizations may work toward devising novel weapons by using techniques like the clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated proteins (Cas) gene editing or synthetic biology technology to enhance or combine the characteristics of multiple organisms or toxins.

The most efficient biological agents are transmitted by aerosols. They are more contagious than those dispersed by other methods and have the capacity to spread over a much larger targeted area. Under optimal conditions, aerosolized dispersion can affect large numbers of individuals, animals, or crops. For example, in the 1960s, the U.S. Army released *Bacillus atropeus* (formerly *B. globigii*), a nonpathogenic surrogate of *B. anthracis*, into the New York City subway system. Calculations performed subsequently indicated that over 10,000 people would have died if *B. anthracis* had been used. If such an experiment were repeated today, the number of fatalities would be much higher because of the larger population.

A main factor that determines the effectiveness of agents aerosolized outdoors is the weather. Wind currents can carry the infectious particles far from the target site, or sudden rainfall could cause the agent to fall to the ground. Agents could also be inactivated by extreme temperatures and ultraviolet (UV) light from the sun. Because bacterial spores, such as those of *B. anthracis*, are resistant to environmental stress (e.g., extreme temperatures, UV light, drying), spores are particularly attractive as bioterror agents. There is difficulty in producing even-sized particles that would be small enough to enter the alveolar air sacs and cause infection. The ideal size would be 1 to 5 μm . Particles larger than 5 μm clump together and are filtered by the upper respiratory tract or settle to the ground more quickly. Particles smaller than 1 μm are just exhaled. Thus the ideal person-to-person spread, such as with smallpox virus and **pneumonic plague** bacteria, would result from uniformly sized, 2- to 3- μm agents prepared for aerosolization.

The detection of a possible bioterror event therefore requires air, food, and water surveillance programs, laboratory scientists trained to recognize potential bioterror agents, and communication with clinicians, emergency response personnel, and infectious disease specialists. The LRN is an important

Case check 30.3

BSL-2 is recommended for activities using clinical materials and diagnostic quantities of infectious cultures. Occasionally, a potential bioterror agent, such as *B. anthracis*, may be isolated from a patient specimen under these circumstances. Because these are actively growing cultures, there is no need for the organism to sporulate. By using standard microbiological procedures, such organisms can safely be ruled in or out and referred to a public health laboratory for additional testing, if warranted. BSL-3 laboratory conditions are required to protect laboratory staff when there is a chance of aerosolization, especially when suspicious powders are tested. Environmental samples should be tested only by certified public health laboratories. The Case in Point demonstrates that the BSL-2 clinical laboratory is adequate for the initial clinical detection of most potential bioterror agents.

source of microbial surveillance and training programs for laboratorians, health care providers, and first responders. The ongoing need to maintain diligent surveillance and state-of-the-art response capabilities requires that all first responders and laboratory scientists be also trained in the best practices of biosafety.

Biological risk management

Bioterrorism can appear to be a natural disease outbreak, and a natural disease outbreak can initially appear as bioterrorism. As a result, the clinical laboratory scientist should be prepared to evaluate the clinical specimen through the lens of **biorisk**. The spectrum of biorisk extends from the naturally occurring disease outbreak (or pandemic) to the intentional misuse of infectious agents. Between these two possibilities are a potential reemerging infectious disease, an unintended

consequence of research, and a laboratory accident. Each of these events presents the clinical laboratory with unique challenges. Imagine the risk associated with processing an average day's number of specimens only to encounter a SARS-like virus or a tuberculosis (TB) agent that day. Although we should always practice good microbiologic technique, a thorough understanding of the risk each specimen presents is best practice for every laboratory scientist.

Biorisk management is the management of risk associated with potential accidental release or exposure of biological agents through the integration of policies, practices, facility design, and safety equipment to enable an organization to effectively identify, assess, control, and evaluate the biosafety and biosecurity risks inherent in its activities. Biorisk management is grounded in the hierarchy of controls in which minimization of the risk is achieved first through elimination or substitution of the risk-causing material or process. If this

is not possible, then the risk is attempted to be minimized using a combination of engineering, administrative, or protective equipment controls. These controls establish specific room design, personal protective equipment (PPE), and standard operating procedures that decrease the risk of personnel and environmental exposure to the agents processed in a laboratory. Thus biological risk management increases the effectiveness of biosafety and biosecurity practices.

Biosafety

Implicit in our discussion of bioterrorism is the concept that agents misused for this purpose are chosen specifically because of their virulence, incubation period, lack of immunity, and thus, ability to incite fear and panic. Therefore the medical laboratory scientist should have a thorough understanding and appreciation of the principles and best practices required to remain safe from such agents in the clinical laboratory. A detailed guidance document produced by the CDC and recommended for all microbiology laboratories for assistance with safe work practices, PPE, and required engineering controls can be found in the most current edition of *Biosafety in Microbiological and Biomedical Research Laboratories* (BMBL).

In sum, **biosafety** is the application of laboratory practice and procedure, specialized laboratory facilities, and safety equipment used when working with potentially infectious material to reduce the risk of a laboratory-acquired infection. Although it is true that the agents often thought to be selected for bioterrorism are lethal, many of the common pathogens passing through hospital laboratories today are sufficiently virulent to produce outbreaks when they are evaluated and tested outside a biological safety cabinet. Therefore it is important to follow the CDC, World Health Organization (WHO), and ASM recommended practice of completing a **biological risk assessment** before performing any work with potentially infectious materials. The risk assessment process is an opportunity for the laboratory scientist to review information about the microorganisms, protocols, antimicrobial susceptibilities, PPE, respiratory protection, and so on to ensure the safest working conditions and to mitigate the consequences of the biohazard.

Regardless of risk group, microbiologists adhere to several basic safety principles to reduce exposure and prevent cross-contamination. These “standard microbiological practices” include frequent handwashing and no eating, drinking, gum chewing, or application of cosmetics in the laboratory. Mouth pipetting should not be performed. Aerosol generation should be avoided in the open laboratory. Personnel should be fully knowledgeable about the microorganism and trained on the procedure. They should use PPE, based on risk assessment results, follow standard operating procedures to reduce guesswork, and perform appropriate decontamination of work areas.

Biosafety levels

Laboratories can be placed into one of four **biosafety levels (BSLs)** based on the microorganism(s) encountered and the procedures with which the microorganisms will be manipulated (Table 30.2). A BSL reflects the microorganism **risk group**, along with a combination of standard procedures and

Table 30.2 Recommended biosafety level practices

BSL	Safety practices
1	Standard microbiological practices
2	BSL-1 practice plus limited access, biohazard warning signs posted, “sharps” precautions, biosafety manual defining standard operating procedures, and any needed waste decontamination or medical surveillance policies
3	BSL-2 practice plus controlled access into the laboratory, decontamination of all waste exiting the laboratory, decontamination of laboratory clothing before laundering, and baseline serum antibody analysis specific to agents used in the laboratory
4	BSL-3 practices plus clothing change before entering the laboratory, showering on exiting the laboratory, and all material decontaminated on exiting the facility

BSL, Biosafety level.

techniques, safety equipment, and facilities designed to minimize the exposure of workers and the environment to infectious agents.

Microorganisms are categorized on an increasing scale of 1 to 4 based on the risk they pose to human health and safety. Risk group 1 organisms are not known to consistently cause disease in healthy adults. Risk group 2 organisms are associated with human diseases. These are the organisms most often evaluated as part of the disease identification process in the clinical microbiology laboratory. They are hazardous to the laboratorian should they be ingested, exposed to a mucous membrane, or enter the host by percutaneous injury. Risk group 3 organisms are also associated with human diseases and can cause serious and even fatal consequences. They are indigenous or exotic agents with the potential for aerosol transmission. Risk group 4 viruses (there are no risk group 4 bacteria yet) are dangerous and often exotic and pose a high risk of life-threatening human diseases. They are readily transmitted by aerosol or direct contact.

Importantly, the organism risk group does not automatically equate to the BSL of the laboratory in which it is manipulated. Because BSLs are defined according to the risk group of the organism that is studied or tested *and* the procedures used, some organisms can fall under more than one BSL category based on the extent of studies. For example, *Mycobacterium tuberculosis* is a risk group 2 microorganism in clinical laboratories that perform only direct examination of clinical specimens. As such, those examination studies can proceed at BSL-2. Laboratories that concentrate TB bacteria, manipulate cultures, and create an aerosolization risk should perform these procedures in a BSL-3 containment facility. It is important to remember that each higher level includes additional safety equipment, precautions, engineering, and work controls over the previous level.

As mentioned earlier, the original list of select agents likely to be used as weapons of bioterrorism was created in 1999. The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 authorized Congress to create a regulatory body that held authority to create and enforce regulations dealing with select agents and toxins. The Federal Select Agent Program became that body. The CDC oversees select agents and toxins that cause disease

in humans, while the U.S. Department of Agriculture oversees the select agents and toxins that affect plants and animals. Agents that cause disease in people and animals are overseen by both agencies. The 2010 Executive Order 13546 required the Select Agent Program to streamline policies and tighten perceived security breaches. In 2012, the biological select agents and toxins list was reevaluated. Some agents were removed, while others were reassigned to a new tiered list based on (1) the potential for causing death, (2) endemicity in the United States (animal agents), and (3) the potential of producing quantities necessary for a high consequence event (see Table 30.1). **Tier 1 agents** that cause human disease include *Bacillus anthracis*, *Burkholderia mallei*, and *B. pseudomallei*; *Clostridium botulinum* neurotoxin-producing strains; *Francisella tularensis*; *Yersinia pestis*; EBOV; Marburg virus (MARV); and variola viruses.

Case check 30.4

B. anthracis falls under the biological agent category because of its natural occurrence in the environment and ability to cause disease and death. It can be easily and inexpensively cultivated and has been demonstrated to cause disease via the respiratory tract, gastrointestinal (GI) tract, and abraded skin. Because *B. anthracis* can produce spores, this organism can survive very harsh conditions and remain infectious. The Case in Point is an example of an individual who was infected by inhalation of anthrax spores and became ill shortly thereafter.

Agents of bioterror

Bacillus anthracis

B. anthracis is an aerobic, gram-positive rod that produces endospores. Anthrax, the disease caused by *B. anthracis*, is primarily a disease of herbivores affecting mainly cattle, sheep, and goats. It has also been termed *wool sorter's disease* or *rag picker's disease* as the spores trapped in wool or on pelts can be transmitted to humans. Anthrax derives its name from the Greek word for coal, based on the characteristic black, necrotic, ulcerative skin lesion (eschar) noted in patients with cutaneous anthrax. Infected animal carcasses seed the soil with vegetative bacilli.

A key feature of *B. anthracis* is its ability to sporulate in response to poor growth conditions, imparting resistance to biological extremes of heat, cold, pH, desiccation, chemicals, irradiation, and other adverse conditions. These organisms can survive for years until taken up by another host, when germination and multiplication can resume. Natural infections in humans usually occur because of interactions with animals or contaminated animal products. Other than infections caused by the mailed spores, anthrax infections in humans have been rare (one or two cases per year) in the United States for at least the past century. Most cases have been cutaneous. Until the anthrax attacks in 2001, the last reported case of **inhalation anthrax** occurred in 1978. Twenty-two cases of anthrax were caused by the 2001 terrorist attack. In 2004, *Bacillus cereus* biovar *anthracis* was recognized as causing an anthrax-like disease in gorillas and chimpanzees in Cameroon and Côte d'Ivoire. Even though as of 2021 no human infections by this

agent have been identified, it was still added to the Tier 1 Select Agent list in 2016. The CDC determined that this bacterium has all the virulence determinates and biothreat potential of *B. anthracis*.

Clinical manifestations

Once inside the host, *B. anthracis* spores are phagocytosed by macrophages. Spores germinate into vegetative cells, capable of producing toxins and resisting phagocytosis. *B. anthracis* produces two plasmid-encoded virulence factors: a three-protein A/B exotoxin (A₂B) and a polypeptide capsule. The plasmid pX01 encodes genes for three specific components of the anthrax toxin: lethal factor (LF), edema factor (EF), and protective antigen (PA). Both LF and EF become biologically active toxins when combined with PA. The plasmid pX02 encodes genes to form a polypeptide (poly-D-glutamic acid) capsule made by the vegetative bacteria, which inhibits phagocytosis.

Human cases of anthrax can be distinguished by their method of exposure, which are typically occupational in nature, industrial (individuals who process bones, hides, wool, or other animal products), and nonindustrial (farmers, veterinarians, butchers). There are three main routes of exposure: cutaneous, ingestion, and inhalational. Worldwide, cutaneous anthrax is the most common form of the disease, accounting for about 95% of all cases. The disease occurs after a minimum of approximately 8000 spores are introduced into cuts or abrasions of human skin. After 1 to 6 days, a papule appears and then progresses to a 1- to 2-cm vesicle within the next 48 hours. When the vesicle ruptures, the resulting necrotic lesion develops into the characteristic black **eschar**, which can be edematous, but is usually painless (Fig. 30.4). The lesion usually heals without incident. The patient may or may not have systemic symptoms. Mortality associated with cutaneous anthrax is less than 1% with appropriate antimicrobial therapy but can be as high as 20% without treatment.

Oral or GI anthrax occurs when anthrax spores are introduced into the tissues of the GI tract, often by eating meat containing anthrax spores. There are two distinct manifestations: oropharyngeal, in which the lesion is localized in the

Fig. 30.4 Cutaneous anthrax lesion on the skin of the forearm. (Courtesy James H. Steele and Centers for Disease Control and Prevention, Atlanta, GA.)

buccal cavity, tonsils, or posterior oropharyngeal wall, and GI, which can occur anywhere within the remaining GI tract. After an incubation period of 2 to 6 days, the patient may experience sore throat, difficulty swallowing, swollen lymph nodes (oropharyngeal anthrax), and nausea and vomiting, rapidly progressing to fever, bloody diarrhea, ascites, and often sepsis (GI anthrax). Intestinal anthrax has a variable mortality rate because of the delayed initiation of appropriate therapy, often because of the nonspecific early symptoms.

Inhalational anthrax occurs when a patient inhales *B. anthracis* spores, typically from an animal or environmental source. Person-to-person transfer is uncommon. Inhalational anthrax is the form of anthrax most likely to be seen in a bioterror event because of the aerosol dispersion of anthrax spores. Spores that are 1 to 5 μm in size can reach the alveoli of the lung. Alveolar macrophages phagocytose the spores, which are transported to the mediastinal lymph nodes. After an incubation period of 1 to 6 days, patients develop nonspecific flu-like symptoms with fever, malaise, and fatigue as vegetative *B. anthracis* cells invade the bloodstream from the lymph nodes. Respiratory symptoms become more severe within the next few days as the patient experiences acute respiratory distress.

The differential diagnosis includes other causes, but the chest x-ray of an anthrax patient shows **mediastinitis** (Fig. 30.5). Pneumonia does not usually result from pulmonary infection. Data from the accidental spore release in Sverdlovsk, Russia, in 1979 suggest that pulmonary anthrax can result from inhalation of 1 to 10 viable spores, leading to a mortality rate of almost 100% without treatment. Because of rapid diagnosis and effective treatment, the mortality rate of inhalational anthrax in 2001 in the United States was less at 45% (5 of 11).

B. anthracis has always been listed as a select agent likely to be used for bioterrorism. The accidental release of spores

at Sverdlovsk, the largest documented outbreak of human inhalation anthrax, demonstrated the potential for misuse. Because most cases are associated with cutaneous exposure, whenever an individual develops a GI or inhalational form of disease, it is important to rapidly distinguish between a natural exposure and a deliberate release. Recent cases of naturally acquired noncutaneous anthrax have increased concerns. Some notable cases include drum makers who developed inhalational anthrax from working with contaminated animal hides, an individual who ingested airborne spores while participating in a community-wide drumming ceremony and developed GI anthrax, and an outbreak of anthrax septicemia or wound infections in the United Kingdom among intravenous (IV) drug users injecting contaminated drugs. Further investigations into these cases found only individuals or similar groups of people who became infected via natural causes. However, the massive exposures that can be created in deliberate release scenarios cannot be emulated by nature.

Specimen collection and preparation

The specimen of choice for cutaneous anthrax diagnosis is vesicular fluid from fresh vesicles. Swabs can also be used to collect material from under the edge of the crust of the eschar. The specimen of choice for diagnosis of patients with GI anthrax is blood, before antimicrobial therapy. Ascites fluid is used for cultures and real-time polymerase chain reaction (rtPCR). Stool and rectal swabs can also be cultured and tested by rtPCR. The specimen needed to diagnose inhalation anthrax is also blood. Because inhalation anthrax usually does not result in pneumonia, and vegetative bacteria are not likely to be found in the lungs, the usefulness of sputum specimens is less than that of blood. Cerebrospinal fluid (CSF) from patients with meningeal signs is also useful for culture and rtPCR.

Direct examination and initial culture

Smears from lesion fluid, eschar, blood, CSF, or tissues may show large, square-ended, boxcar-like gram-positive bacilli. There may be evidence of a capsule around the cells. Spores most likely will not be evident in direct smears from clinical specimens because spores form only in poor nutritional environments.

In aerobic culture, *B. anthracis* will yield large (2 to 5 mm) nonhemolytic colonies on 5% sheep blood agar (SBA). Colony growth can be rapid and occur in as little as 8 hours. Mature colonies have a ground-glass appearance. The colony often has feathery projections coming from the margin, referred to as *Medusa-head* colonies (Fig. 30.6). Colonies also have a tenacious consistency, which—when teased with a loop, for example—will form peaks, like whisked egg whites (Fig. 30.7). The gram-positive bacilli (Fig. 30.8) can show oval endospore formation in late-stage cultures (Fig. 30.9). The spores are central or subterminal and do not cause the bacterial cell to swell.

Tests for presumptive identification

According to CDC protocols, a presumptive identification of *B. anthracis* can be made if an isolate has the following characteristics: (1) aerobic growth and (2) nonhemolytic colonies 2 to 5 mm in diameter containing catalase-positive, nonmotile,

Fig. 30.5 Chest radiograph of a patient who worked in a goat hair processing mill. Note the widened mediastinum, often seen with inhalation anthrax. (Courtesy Arthur E. Kaye and Centers for Disease Control and Prevention, Atlanta, GA.)

large gram-positive bacilli recovered from lesions, blood, CSF, or lymph nodes. Oval, central to subterminal spores may be present. Other bacilli, such as *Bacillus cereus* var. *anthracis* and *Bacillus cereus* var. *mycoides*, can also have this profile. *Bacillus megaterium* is often confused morphologically for *B. anthracis*. Organisms with a presumptive identification of *B. anthracis* must be sent immediately to an LRN reference laboratory for confirmatory identification. The recovery of *B. anthracis* in inhalational or GI anthrax is a sentinel event in the United States.

Case check 30.5

According to the requirement of the Select Agent Program, the clinical laboratory in the Case in Point that isolated the *B. anthracis* from the hospitalized patient should ship all isolates of the organism to its state laboratory and destroy such isolates within 7 days of confirmation by that state laboratory.

Burkholderia species

The genus *Burkholderia* contains two species considered to be potential agents of bioterrorism: *B. mallei* and *B. pseudomallei*. *B. mallei* causes the disease known as **glanders**; *B. pseudomallei* is the causative agent of **melioidosis**. *B. mallei* has disappeared from most regions of the world. However, it is enzootic in Asia and several eastern Mediterranean countries, where environmental isolates have been recovered from soil and water. Sporadic cases among those whose occupations involve contact with infected horses, mules, and donkeys and in laboratory scientists have been reported in the Western Hemisphere. Glanders manifests itself in three forms: (1) a chronic pulmonary form with cough, producing a mucopurulent sputum; (2) a form characterized by abscesses of the skin, subcutaneous tissues, and lymphatics, known as *farcy*; and (3) an acute septicemic form that rapidly progresses from

fever, chills, and prostration to death, within 7 to 10 days. The disease does not appear to be readily transmitted from person to person, although two human cases of transmission by sexual and direct contact have been reported in the literature.

Melioidosis, caused by *B. pseudomallei*, is a disease similar to glanders but found in different parts of the world. *B. pseudomallei* is endemic to Southeast Asia (particularly Thailand), the South Pacific, Africa, India, and the Middle East. Although not as common, the organism has been isolated from patients in Mexico, Panama, Peru, and Haiti. The organism has also been recovered from patients in Hawaii and Georgia. Approximately one to five cases are reported in the United States each year and are primarily travel related. This organism is a saprophyte found commonly in soil and water.

Clinical manifestations

The infectious doses of *B. mallei* and *B. pseudomallei* are not known but are thought to be low because of the ease of infectivity. The incubation periods are variable, ranging from 1 to 14 days. Disease in humans depends on the route of transmission. Symptoms of infection include fever, myalgia, headache, and chest pain. Infection can result in localized cutaneous lesions, septicemia, and pneumonia. Bloodstream infections are often fatal. Although a human case of laboratory-acquired infection with *B. mallei* was documented in Maryland in 2000, no naturally acquired cases of human infection with *B. mallei* have been recorded in the United States since 1945.

Transmission of *B. pseudomallei* is usually related to contact with soil and water, direct contact with infected animals, or inhalation. Rare, documented cases of person-to-person transmission, primarily through blood and body fluids, have also been reported. Clinical infection is similar to that of glanders in humans. If the patient is infected via direct contact and bacterial entry occurs through broken skin or mucous membranes, the clinical presentation is a localized nodule. However, hematogenous dissemination can also occur, resulting in acute sepsis. Bloodstream dissemination of the organism can result in a chronic form of melioidosis, with lesions forming at multiple internal organs. If the organism enters via inhalation, the clinical presentation can range from mild bronchitis to severe lower respiratory tract infection.

More recent case reports have identified latent infections in which clinical infection manifests itself between the fourth and fifth decades of life in patients with underlying complications of diabetes mellitus, excessive alcohol consumption, chronic renal failure, and chronic lung disease. In the United States, many of the reported cases were noted in war veterans who had served in Vietnam years earlier and developed signs and symptoms of disease, likely because of a waning immune status. This condition has been termed the *Vietnamese time bomb*, indicating that the patient was likely infected years earlier, but because of age and risk factors noted, the disease is a reactivation of a latent infection.

Specimen collection and preparation

Because laboratory transmission is a high risk with culture and manipulation of these organisms, health care providers suspecting infections by *B. mallei* and *B. pseudomallei* should notify the clinical laboratory when submitting specimens for

testing. Specimens appropriate for submission to detect either of these isolates are blood, bone marrow, sputum, bronchoalveolar lavage, abscess material, urine, and serum. Automated identification systems should not be used if *Burkholderia* spp. are suspected.

Direct examination and initial culture

Direct Gram-stained smears of aspirates and respiratory secretions will reveal gram-negative coccobacilli for *B. mallei* and small gram-negative bacilli for *B. pseudomallei*. These organisms will also be noted on direct smear examination of blood cultures from these patients. If *B. mallei* or *B. pseudomallei* is suspected, cultures are incubated at 35°C in 5% carbon dioxide (CO₂) for up to 5 days. *B. mallei* grows as small, circular, butyrous colonies after 24 to 48 hours of incubation on SBA. If held longer, the colonies will gradually convert to a dry, wrinkly appearance, resembling those of *Pseudomonas stutzeri*. *B. mallei* and *B. pseudomallei* typically grow on MacConkey (MAC) agar and SBA (Fig. 30.10). *B. pseudomallei* and *B. mallei* colonies resemble each other. *B. pseudomallei* may produce a smell like that of soil; however, smelling bacterial colonies with the plate open is hazardous and should never be attempted.

Tests for presumptive identification

Gram-negative coccobacilli or small gram-negative bacilli with poor growth at 24 hours forming larger nonpigmented gray colonies at 48 hours that are indole negative, nonmotile, catalase positive, and resistant to polymyxin B or colistin are presumptively identified as *B. mallei* and must be submitted immediately to the nearest LRN reference laboratory. Gram-negative coccobacilli or small gram-negative bacilli that exhibit poor growth at 24 hours but form larger nonpigmented gray colonies at 48 hours, begin to wrinkle after 48 hours, grow on MAC agar, are oxidase positive and indole negative, and are resistant to polymyxin B or colistin cannot be ruled out as *B. pseudomallei*. An isolate with these characteristics should be referred to an LRN reference laboratory for confirmation.

Clostridium botulinum neurotoxin

Clinical manifestations

Botulinum toxin is a neurotoxin primarily produced by *Clostridium botulinum*, although other clostridia, including *C. butyricum* and *C. baratii*, can also produce the toxin. Seven main types of toxins, designated A to G, are well known, although new types are occasionally found. The types commonly implicated in human disease are A, B, E, and rarely F.

C. botulinum spores can be recovered from soil specimens throughout the world. Although rare in the United States, naturally occurring botulism cases do occur. There are four typical manifestations of disease: foodborne botulism, infant botulism, intestinal botulism caused by bacterial colonization in children and adults, and wound botulism. The CDC has kept national botulism surveillance since 1973; an average of 163 U.S. cases of botulism were reported annually between 2001 and 2020, with most cases occurring in infants. Foodborne botulism occurs when *C. botulinum* spores survive in poorly washed and improperly preserved or canned food products. The spores germinate under anaerobic conditions, inside the food container, into vegetative cells producing neurotoxin. Consumption of the toxin-tainted food leads to disease; this is an example of intoxication with bacterial toxin. The most commonly associated foods are home-canned vegetables, meats, smoked or raw fish, and honey or corn syrup.

Infant botulism is the most commonly recognized form and typically affects infants between 3 weeks and 6 months of age. Infection occurs when the child ingests a spore via soil exposure or contaminated foods, such as raw honey. In this case, a true infection occurs when the spore germinates, and vegetative bacteria colonize the intestinal tract. Infants who are formula fed are most prone to this because their still maturing gut microbiota is unable to fend off this infection. Adult-onset botulism, resulting from infection, is similar to the infant form; their gut microbiota is also unable to prevent infection, typically because it has been compromised by administration of antimicrobial agents or surgery. Wound botulism occurs when a spore enters an open wound, converts to a vegetative cell, and proliferates, producing the toxin. This type of infection has most commonly been recognized in IV drug users.

Adults are more likely to have intoxication botulism. The period between exposure and symptoms differs depending on the route of exposure, the form of disease (i.e., intoxication or infection), and the amount of toxin. For example, an ingestion toxemia might take from 2 hours to 8 days; the average, however, is 18 to 36 hours. Fever is absent, and patients often develop trouble speaking, swallowing, and seeing (blurred vision). The toxin causes a descending, progressive, bilateral muscle weakness resulting in flaccid paralysis, ultimately ending with respiratory failure and death. Disease mortality can be 25% but more typically is only 5% to 10% when medical intervention, such as mechanical ventilation or intubation, is provided promptly. The toxin irreversibly binds to neurotransmitters, so antitoxin and a toxoid vaccine should be administered immediately if botulism is suspected. Some hallmark features of infant botulism include slowed breathing, poor feeding, constipation, weak cry, loss of head control, and essentially a floppy appearance (Fig. 30.11).

Botulinum toxin is the most lethal of all biological agents; the lethal dose that kills 50% of test animals is **1 ng per kilogram of body weight**. If a single gram of crystalline toxin

Fig. 30.11 A 6-week-old infant with botulism caused by ingestion of *Clostridium botulinum* spores, noted by loss of muscle tone in the head and neck areas. (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

were optimally dispersed over a city, it is estimated that there would be over 1 million deaths. It has been further estimated that based on its lethal dose, **8 oz would be enough to kill nearly every human on the planet**. Wound-associated cases are not likely to be associated with a terrorist attack; it is more likely that larger-scale inhalation or foodborne ingestion of the toxin would be a biocrime.

Specimen collection and diagnosis

Because of its rapid effects, an initial diagnosis of botulinum toxin exposure should be based on symptoms, as opposed to laboratory data. Thus treatment should begin before laboratory confirmation. The LRN stresses that botulism is a public health emergency and that local and state public health officials should be notified upon diagnosis. Most local hospitals are not equipped to process specimens for the detection of botulinum toxin; therefore specimens should be submitted to the nearest LRN reference laboratory. Specimens appropriate for referral include feces, gastric aspirate or vomitus, serum, tissues or exudates, and suspected food specimens. Environmental specimens should also be submitted to the LRN reference laboratory, if possible.

Diagnosis of botulism can be confirmed by the detection of organisms in culture or botulinum toxin in specimens. The traditional method that confirms botulinum toxin and identifies the serotype is a mouse toxicity assay. Some enzyme immunoassay tests are sensitive enough to detect the minute amounts of residual toxin found in the respiratory tract of affected patients. LRN reference laboratories also use rtPCR to confirm the detection of botulinum toxin.

Ebola virus and Marburg virus

EBOV and MARV are zoonotic pathogens that cause severe hemorrhagic fever in humans. They are members of the virus family *Filoviridae*, sharing some common

Fig. 30.12 Transmission electron micrograph of an Ebola virus virion (causative agent of hemorrhagic fever) by negative stain technique ($\times 100,000$). (Courtesy Dr. Fred Murphy and Centers for Disease Control and Prevention, Atlanta, GA.)

characteristics. By electron microscopy, the filoviruses have a distinctive ropey appearance that makes them easily recognizable. They are pleomorphic, filamentous particles that may be coiled, toroid, or branched; thus they can assume different shapes, such as a shepherd's crook, a number 6, and a letter U (Fig. 30.12). They are relatively small (80 to 1200 nm, larger when grown in tissue culture), enveloped, single-stranded ribonucleic acid viruses that require an animal host as a reservoir. The natural reservoirs of these viruses have still not been determined. However, humans are not the natural reservoir for either of these viruses; rather, humans become infected when they encounter the natural host or another animal infected with the virus. Importantly, subsequent person-to-person transmission can occur without strong public health measures in place to contain the disease. Contact with nonhuman primates appears to be instrumental in several EBOV outbreaks, but the primates are not the natural reservoir. Some evidence indicates a role for bats in the persistence of EBOV in the environment. Airborne or droplet transmission is not considered a common natural route of transmission of EBOV and MARV. Direct contact with infected body fluids seems to be the primary mode of transmission; therefore effective use of PPE and "contact precautions" generally stops the transmission chain.

There are six known species of the genus *Ebolavirus*; five of them are well characterized, and four cause human disease. They are (1) *Zaire ebolavirus* (ZEBOV), the cause of most outbreaks, 70% to 90% fatality rate; (2) *Sudan ebolavirus* (SUDV), 53% to 68% fatal; (3) *Reston ebolavirus* (RESTV), a nonhuman pathogen; (4) *Tai Forest ebolavirus* (TAFV), formerly *Cote d'Ivoire ebolavirus*, unknown human pathogenicity; (5) *Bundibugyo ebolavirus* (BEBOV), 34% fatal; and (6) *Bombali ebolavirus* (BOMV), unknown human pathogenicity. EBOV was first recognized during epidemics in Sudan and the Democratic Republic of the Congo (formerly Zaire) in 1976. EBOV has made a deadly appearance nearly every year since then. Significantly, 32,377 cases of EBOV disease were reported

from 2014 until the end of 2020, with an average mortality rate of 43%. Clearly the filoviruses present a huge challenge when preparing for bioterrorism because of the frequency with which these highly pathogenic viruses erupt into the world, the fatality rates that they produce, and the fear that they command.

Marburg virus disease was first described in 1967 during concurrent outbreaks in Marburg and Frankfurt (Germany) and Belgrade (Yugoslavia, now Serbia) resulting from laboratory-acquired transmission from African green monkeys imported from Uganda. Two viruses that share more than 90% nucleotide homology cause Marburg disease. Both are of the genus and species *Marburg marburgvirus*. In 2009, the Egyptian rousette, or Old-World fruit bat, was found to harbor both strains of *M. marburgvirus*, implicating it as a potential reservoir host. Since its discovery, at least 10 outbreaks of Marburg disease were recorded through 2014, including two (1988 and 1990) in Koltsovo (in the former Soviet Union) purportedly resulting from laboratory accidents. There are two MARVs that cause Marburg virus disease: Ravn virus (RAVV) and MARV. Because the genomes of both viruses diverge by <10% from the prototype *Marburg marburgvirus*, they are considered to both be strains of MARV.

The U.S. Food and Drug Administration (FDA) licensed a vaccine for the *Zaire ebolavirus* in 2019. It is a replication-competent, live, attenuated, recombinant vesicular stomatitis virus (rVSV) vaccine. This vaccine has yet to be tested against other filoviruses. There are also two biologic drugs licensed by the FDA to treat *Zaire ebolavirus*. The first drug is a combination of three monoclonal antibodies. The second drug is a single monoclonal antibody. They have yet to be approved for disease caused by other filoviruses. Experimental small drug molecules for both EBOVs and MARVs are in development.

Clinical manifestations

Clinical manifestations of these infections differ depending on several factors, including viral strain. In general, the infectious dose for EBOV and MARV is 1 to 10 infectious particles. The incubation period for most of these infections is 4 to 22 days, after which the patient may experience some or all of the nonspecific symptoms, such as fever, rash, myalgia and arthralgia, nausea, conjunctivitis, diarrhea, and central nervous system symptoms (headache, meningitis). Hemorrhagic fever is not as common a manifestation as with other filoviruses. Infections can include a varied degree of bleeding disorders, ranging from disseminated intravascular coagulation (DIC), petechiae, and hemorrhage of the mucous membranes to conjunctivitis, blood-tinged urine, and blood-tinged vomitus. Generally, patients infected with these filoviruses might be febrile and have a maculopapular rash, bleeding, and DIC.

Specimen collection and preparation

Specimens should not be collected from patients with suspected EBOV or Marburg disease or processed until after consultation with public health officials. Specimens appropriate for the diagnosis of EBOV or MARV disease include serum, heparinized plasma, whole blood, respiratory aspirates, tissue, and urine.

Francisella tularensis

Tularemia is a plaguelike, zoonotic disease caused by *F. tularensis* that was first isolated in 1911, when it was found to be the cause of an outbreak in ground squirrels in Tulare County, California. *F. tularensis* is distributed across the entire Northern Hemisphere. Natural infections occur annually in various parts of the world. In the United States, 2537 cases were reported from 2007 to 2020.

Human infections usually occur by accidental contact with the organism, via arthropod bite, by direct contact with infectious materials, by ingestion of contaminated food or water, or by inhalation of infective aerosols. Hunters or outdoor enthusiasts typically have a higher rate of infection because of contact with infected carcasses and animals or vectors, including ticks, mosquitoes, and flies. Because of the numerous ways this infection can be transmitted, tularemia has numerous nicknames to match, including *deer fly fever*, *rabbit fever*, *Ohara fever*, *market men's disease*, and *water trapper's disease*. The most common U.S. reservoirs are several species of ticks (e.g., *Ixodes*, *Amblyomma*, *Dermacentor*, *Haemaphysalis*) and numerous other arthropods. The most common mammal associated with tularemia in the United States is the rabbit.

The infectious dose for the bacterium causing cutaneous or inhalational disease in humans is as low as 10 to 100 organisms. Natural infections resulting from aerosolized *F. tularensis* have been described, often from handling contaminated hay, mulch, water, or infected carcasses. An interesting case of pneumonic tularemia was recorded when two adolescents became ill after mowing a grassy area. The high degree of infectivity, incapacitating nature, and natural occurrence of the organism has marked it as a potential biological weapon. The WHO estimates that 50 kg of organism could infect 125,000 people in a city of 5 million people and could cause up to 19,000 deaths.

Clinical manifestations

Tularemia has different clinical manifestations. The most usual clinical presentation is ulceroglandular disease, during which the organism is transported to the local lymph nodes and disseminated throughout the bloodstream. The naturally occurring infection results from inoculation of the organism into the dermis of the patient (Fig. 30.13). Inoculation occurs via the bite of a *F. tularensis*-infected arthropod or from handling infectious materials. The latter is common among those engaging in outdoor sports. The ulceroglandular form has an incubation period ranging from 2 to 10 days, with an average of 3 to 4 days, after which patients become abruptly febrile, with chills, headaches, cough, and chest pain. Patients develop lesions at the site of entry, and these are slow to heal and can persist for weeks to months.

The glandular form occurs when organisms are transported to lymph nodes, causing lymphadenopathy, similar to the buboes of bubonic plague. Hematogenous dissemination can occur, resulting in multiorgan seeding. Even without antimicrobial therapy, patients who progress to this point rarely die of this form of the disease. Symptoms resolve over a period of months, but the patient experiences malaise, anorexia, fatigue, and weight loss.

Less commonly, patients develop oculoglandular, oropharyngeal, GI (on ingestion of contaminated materials), or inhalational disease. In the event of inhaling an aerosol of *F. tularensis*, patients develop pneumonic or

Fig. 30.13 Poorly healing ulcerative lesion of tularemia on the thumb. (Courtesy Dr. Thomas Sellers, Emory University, and Centers for Disease Control and Prevention, Atlanta, GA.)

inhalational tularemia. Fever and symptoms of a lower respiratory tract infection, essentially a flulike disease, can rapidly progress to dyspnea, hemoptysis, sepsis, meningitis, and shock. Chest radiography will reveal a widened mediastinum, similar to that seen with inhalation anthrax. Natural cases of inhalational tularemia do occur, usually in rural areas. Mortality rates of untreated inhalational tularemia can be 30% to 60%. In the United States, tularemia has an overall mortality of about 2%.

Direct examination and initial culture

Blood culture specimens are collected from patients with fever. If lesions are present, biopsy or culture specimens from the leading margin of the lesion can be collected and submitted for culture and direct examination. If the clinical presentation or patient history is consistent with tularemia, the laboratory must be notified before the submission of specimens. Specimens should be handled in a biological safety cabinet, and procedures generating aerosols should be performed with BSL-3 safety practices. Several incidents of laboratory-acquired infections have been recorded as workers processed specimens and cultures on an open bench, only later identifying the organism through biochemical testing or PCR.

Tests for presumptive identification

On Gram-stained smears, *Francisella* appears as tiny, pleomorphic, gram-negative coccobacillus (Fig. 30.14). *Francisella* is fastidious, requiring the amino acid cysteine for optimal growth. The organism grows well on media supplemented with cysteine, such as chocolate agar (Fig. 30.15A), modified Thayer-Martin medium, cysteine heart agar, and buffered charcoal-yeast extract agar (see Fig. 30.15B–D). *F. tularensis* grows very slowly, so colonies may not be visible on solid media until after 36 to 48 hours of incubation. Growth may be stimulated with increased CO₂ incubation. *F. tularensis* will not grow at all on MAC agar or eosin-methylene blue agar.

Pleomorphic, poorly counterstaining, gram-negative coccobacilli from blood cultures that do not grow well, if at all, on SBA should lead the laboratory scientist to consider

Fig. 30.14 Micrograph of *Francisella tularensis* demonstrating poorly staining, very tiny (0.2 to 0.7 μm) gram-negative coccobacilli (Gram stain, $\times 1000$). (Courtesy Larry Stauffer, Oregon State Public Health Laboratory, Hillsboro, OR, and Centers for Disease Control and Prevention, Atlanta, GA.)

F. tularensis. As a safety precaution, laboratory procedures must be done inside a biological safety cabinet until *F. tularensis* has been ruled out. Catalase and β -lactamase tests are positive for *F. tularensis*, whereas requirements for X and V factors, urease, and oxidase are negative. Isolates with these reactions are presumptively identified as *Francisella* and should be referred to an LRN reference laboratory for confirmatory identification, usually via PCR.

Variola virus

Variola virus is the causative agent of smallpox. The virus belongs to the family Poxviridae, genus *Orthopoxvirus*. These brick-shaped, double-stranded deoxyribonucleic acid (DNA) viruses measure approximately 200 nm in length (Fig. 30.16). Variola viruses are strictly characterized as risk group 4 because of the planetwide public health risk should they enter the unvaccinated population again. The clinical (sentinel) laboratory does not culture these viruses for identification, and there is no commercially available diagnostic kit for smallpox. The role of the sentinel laboratory is advisory to health care providers recommending specimen collection, packaging, and alerting the LRN.

Fig. 30.16 Transmission electron micrograph of smallpox viruses by negative stain technique ($\times 100,000$). (Courtesy Dr. Fred Murphy and Centers for Disease Control and Prevention, Atlanta, GA.)

Clinical manifestations

Following a successful worldwide eradication program, the last naturally occurring case of smallpox (variola) was reported in 1977. The two major forms of the disease were **variola major** and **variola minor**. Although antigenically indistinguishable, variola minor caused a much less severe disease compared with variola major, with a mortality rate of about 1% compared with about 30% for variola major. Until the late 1800s, variola major predominated. Variola minor was first described in the late 19th century in Africa and the United States. This form of smallpox spread throughout North America and eventually reached Europe. The mortality rate of variola major was about 30% in unvaccinated patients but only about 3% in vaccinated patients. The vaccination consists of an attenuated vaccinia virus. The vaccine can rarely produce infection that is serious or even fatal.

Smallpox was typically transmitted through respiratory droplets via close contact with infected patients or by direct contact with scabs and virus-contaminated fomites. What is more concerning, however, is that the virus can also be spread by aerosol, and the dose required to initiate infection is quite low. Initially, the virus replicates within cells of the oropharynx or respiratory mucosa and later spreads to the regional lymph nodes and multiplies. The infected patient undergoes a transient asymptomatic viremia, resulting in hematogenous dissemination of the virus. About 8 to 10 days after exposure, the patient develops fever and malaise, presenting with a flu-like syndrome. Variola virions infect white blood cells, which are transported to small blood vessels under the dermis and oral mucosa. Oral lesions develop, and the patient is infectious at this point. The patient develops a light macular rash, starting on the head and arms and then spreading to the trunk

Fig. 30.17 Nepalese female demonstrating classic maculopapular rash of smallpox pustules over her entire body. (Courtesy David Bassett and Centers for Disease Control and Prevention, Atlanta, GA.)

and legs. The macular rash then progresses to a vesicular rash after 1 to 2 additional days.

One of the most characteristic signs of smallpox, differentiating it from other viral fevers and rashes, such as chickenpox (varicella), which is caused by a herpesvirus (varicella zoster virus), is the synchronous progression of the lesions; all lesions have almost the same appearance. Also, lesions are more heavily concentrated on the extremities because the virus prefers the cooler body temperature found in these locations. Another significant feature of smallpox is that the palms and soles are not spared, as they are with varicella. Vesicles continue to progress into pustules (Fig. 30.17). The pustules are unique in that they penetrate deeply into the tissue of the patient and are extremely turgid. It is at this stage—approximately 1 week after the start of the rash—that the patient is most likely to die. After about day 14 of the rash, the pustules start to scab and heal, leaving significant scarring. Once all scabs have fallen off, the patient is no longer infectious, whereas the scab material is highly infectious. The surviving patient would likely be immune to future infection by the virus. Variola minor disease is characterized by a less severe presentation, with a less dense rash.

Edward Jenner showed in 1796 that inoculation with the benign cowpox virus conferred resistance to smallpox. During the 19th century, vaccination programs began using the **vaccinia** virus instead of cowpox. In 1967, the WHO began a smallpox eradication program based on detection and vaccination, which ultimately ended smallpox infections globally. The last case of smallpox in the United States occurred in 1949, and the last documented case of natural smallpox was in Somalia in 1977. In 1980, the WHO made the triumphant declaration that the world was smallpox-free. All known stocks of variola were destroyed, except for two. One of the stocks remains at the CDC, and the second is maintained at the Russian State Research Center of Virology and Biotechnology in Koltsovo. There are lingering concerns that other undocumented stocks of smallpox virus may be currently maintained by other countries.

After the *B. anthracis* bioterror attack in the United States in 2001, several countries began stockpiling the smallpox vaccine. The method of vaccination is similar to the original variolation procedure, whereby a bifurcated needle containing a standardized amount of attenuated vaccinia virus is used to inoculate an individual (Fig. 30.18). In 2002 and 2003, a U.S. federal campaign to vaccinate health care workers against smallpox ended when many workers, concerned about

Fig. 30.18 Method of vaccination against smallpox using live vaccinia virus. A bifurcated needle holds a standard amount of virus (A), which is then inoculated into the individual's arm (B). (Courtesy James Gathany and Centers for Disease Control and Prevention, Atlanta, GA.)

potential adverse side effects, shunned the vaccine. Since then, the only persons actively being vaccinated are military service members in preparation for deployment and laboratory scientists working in LRN reference and national laboratories.

Diagnosis of smallpox

Detection and identification of smallpox virus are based on the patient's signs and symptoms, as defined by the CDC's acute, generalized vesicular or pustular rash protocol. Following this algorithm, patients seen by health care providers can be classified as being at low, moderate, or high risk for smallpox. Specimens collected from high-risk patients are transported to the CDC or another national laboratory for variola virus identification. Any individual suspected to have smallpox should be placed in isolation, typically in a negative-pressure room, to protect others against potential aerosol exposure.

Yersinia pestis

Throughout history, plague pandemics have demonstrated the efficacy of *Y. pestis* as an effective human pathogen. Natural outbreaks of plague are subject to international health regulations by notification of the WHO. The first recorded pandemic of plague ("Plague of Justinian") began in Egypt in A.D. 541 and lasted almost 200 years, decimating the human population by as much as 60% throughout North Africa, Europe, and parts of Asia. It is suggested that this event helped usher in the Dark Ages of Europe.

The second plague pandemic started in Asia in 1330 and spread into Europe in 1347. The spread of plague into and throughout Europe may have been facilitated by the Siege of Caffa in 1346. During the next 7 years, the plague killed as many as 20 million to 30 million Europeans, with perhaps another 20 million victims over the next 50 years. Localized outbreaks and smaller epidemics occurred up to the 17th century.

The third pandemic, the Hong Kong plague, began in the mid-19th century in China and lasted approximately 100 years. During the third pandemic, the plague gained access to the United States via ports in San Francisco in the early 1900s.

In 1894, Alexandre Yersin was the first person to describe the plague bacillus and fulfill Koch's postulates linking this organism with **bubonic plague**. The major vector for the plague bacillus is the rat flea, *Xenopsylla cheopis* (see Fig. 30.1), although many other fleas can transmit *Y. pestis*. More than 200 mammals can be involved in the transmission of plague. *Rattus rattus*, the black rat, is the rodent most attributed to urban outbreaks of plague. In the early years of the 20th century, large metropolitan areas along the West Coast of the United States experienced several outbreaks of plague until efforts were made to control or eradicate the rodents.

In the United States, sylvatic plague still occurs in the Southwest desert area, affecting mainly individuals who encounter reservoir hosts through occupational hazards, hunting, or camping. These reservoirs include deer mice, ground squirrels, prairie dogs, and other mammals. The most common vector in the United States is the flea *Diamanus montanus*.

Clinical manifestations

Y. pestis infection occurs in three distinct clinical forms: bubonic plague, septicemic plague, and pneumonic plague. Infections occur as a result of being bitten by an infected flea, handling contaminated materials, or inhaling aerosolized plague bacteria. Natural infections rarely occur in the United States. From 2000 to 2019, 96 cases of plague were reported in the United States, most of which occurred in the western part of the country, from New Mexico and Arizona north to Montana and Wyoming. New Mexico accounted for almost 50% of the reported cases.

Bubonic plague, the most common form of disease, results from the bite of a flea or by direct inoculation of an open skin wound by plague-infected material. As the organisms begin

Fig. 30.19 This patient has an axillary bubo and edema as a result of bubonic plague. (Courtesy Margaret Parsons and Dr. Karl F. Meyer and Centers for Disease Control and Prevention, Atlanta, GA.)

Fig. 30.20 The patient presented with symptoms of septicemic plague that included gangrene of the right hand, with necrosis of the fingers. (Courtesy Dr. Jack Poland and Centers for Disease Control and Prevention, Atlanta, GA.)

to proliferate at the inoculation site, a vesicle or ulcer forms. The plague bacteria are transported via the lymphatic system to the regional lymph nodes, usually the inguinal, axillary, or cervical lymph nodes. As the bacteria multiply, the affected lymph node becomes inflamed and extremely painful, forming the characteristic lymphadenopathy, or bubo, with evident edema (Fig. 30.19). **Buboes**, lymph nodes filled with inflammatory cells that can ulcerate, may be several centimeters in diameter. The location of the developing bubo is a strong indicator of the initial site of infection. Inguinal buboes suggest an infection on the lower extremities, whereas axillary buboes normally result from inoculation on the upper extremities. Although the bubo is a hallmark feature of bubonic plague, patients also experience rapid onset of fever, chills, headache, and general malaise.

In some patients, the lymph nodes become damaged, allowing hematogenous dissemination of the organism, causing secondary septicemic plague. Patients may also develop a primary form of septicemic plague in which no buboes are evident following infection, so the health care provider might not even suspect plague. Patients with the septicemic form of plague have symptoms like those of bubonic plague, but then progressively worsen as bacterial endotoxins trigger an immunologic cascade of events, ultimately leading to multiple organ failure, respiratory distress, and DIC, noted by petechiae and gangrene in the extremities (fingers, toes, and nose; Fig. 30.20). As the bacilli affect other organ systems, especially the lungs, brain, liver, and spleen, the patient can develop a secondary pneumonic plague, with dyspnea and hemoptysis, meningitis, and hepatic and splenic abscesses.

Individuals who develop the pneumonic form of plague are extremely infectious. They should be isolated, and respiratory precautions should be followed to reduce the spread of disease. Health care personnel should ensure that all individuals with close patient contact (within 2 m) wear a mask to avoid inhaling aerosolized plague bacteria and becoming infected. Because *Yersinia* is a nonsporulating, gram-negative organism, it cannot be dried and disseminated as easily as *B. anthracis*; it requires close contact and inhalation of moist contaminated droplets from a point source. If *Y. pestis* were to be weaponized, its optimal release would be via aerosol, and most patients would develop primary pneumonic plague.

This form is easily transmissible from person to person under conditions of close contact, continues the spread of disease, and increases overall mortality rates.

Specimen collection and preparation

Like anthrax, plague can manifest itself in numerous ways. If the patient has respiratory symptoms, lower respiratory tract secretions, such as sputum, bronchial wash, and trans-tracheal aspirate are the specimens of choice. Patients who appear septic and have a fever should have blood drawn for cultures. It is recommended that if *Y. pestis* infection is suspected, one set of blood cultures be held at room temperature because this organism grows faster at 22° to 28°C than at 35°C.

The specimen of choice for patients with buboes would be aspirated lesion fluid from the bubo or a biopsy of the lesion. Early buboes generally have little or no obtainable fluid, so 1 to 2 mL of saline should be injected into the bubo initially and then withdrawn to improve recovery of the organism. Care must be taken to avoid aerosol generation to minimize the risk of transmission during specimen collection.

Direct examination and initial culture

Gram-stained preparations of respiratory secretions, aspirates, and tissues infected with *Y. pestis* will reveal plump, gram-negative rods, approximately 1 to 2 µm by 0.5 µm. They may appear as single cells or in short chains; longer chains can form in liquid media. This organism often shows bipolar staining characteristics; that is, the ends are darker than the middle of the cell, resulting in what is described as a “safety pin” appearance. This staining characteristic is not specific for *Y. pestis* (*Pasteurella* and *Burkholderia* spp. can also display this type of morphology), and the Gram stain may not always be the best choice of stain to reveal the bipolar nature. Smears stained with Wayson or Wright stain may show more of the bipolar staining trait (Fig. 30.21).

Colonies of *Y. pestis* on SBA plates and other solid media develop slowly, requiring incubation for up to 48 to 72 hours for visible colony growth. Colonies are nonhemolytic and can have flattened edges, with a raised center demonstrating a

Fig. 30.21 Wright stain of *Yersinia pestis* from blood of a plague victim. Note the darker stained bipolar ends of the organism, resulting in the classic safety pin appearance. (Giemsa stain, $\times 1000$). (Courtesy Centers for Disease Control and Prevention, Atlanta, GA.)

Fig. 30.22 *Yersinia pestis* on sheep blood agar, 72 hours of incubation. Colonies are gray-white to slightly yellow opaque, raised, with a irregular "fried egg" morphology; alternatively, colonies may have a "hammered copper" shiny surface. (Courtesy Larry Stauffer, Oregon State Public Health Laboratory, Hillsboro, OR, and Centers for Disease Control and Prevention, Atlanta, GA.)

"fried egg" appearance (Fig. 30.22). Older colonies are adherent to the agar, forming sticky, stringy strands when one tries to remove colonies from the plate (Fig. 30.23). Patient specimens inoculated into protein-based or thioglycollate broths may appear as long streamers, connected to the tube and growing into the broth. As these formations break, cottonlike fragments accumulate at the bottom of the tube, so-called *puffballs*.

Tests for presumptive identification

LRN sentinel protocols define a suspected *Y. pestis* isolate as a bipolar staining, nonmotile, non-spore-forming, gram-negative rod producing very small colonies after 24 hours of incubation at 35°C, whereas the colonies may appear slightly larger on plates incubated at room temperature. The organism will grow as small, nonlactose-fermenting colonies on MAC agar. *Y. pestis* is positive for catalase but negative for

Fig. 30.23 Tenacity of *Yersinia pestis* colonies on sheep blood agar, 48 hours of incubation. Colonies are difficult to remove from plate and appear stringlike and sticky. (Courtesy Amanda Moore, Dr. Todd Parker, and Audra Marsh and Centers for Disease Control and Prevention, Atlanta, GA.)

oxidase and urease. Bacteria isolated from blood, respiratory specimens, or lesion aspirates that have these culture characteristics should be referred immediately to an LRN reference laboratory for definitive identification.

Other biological agents and toxins

Several other bacteria, viruses, fungi, and toxins are also select agents (see Table 30.1). Many of these are highly virulent or cause debilitating disease, even death, or they are less virulent but can be produced in large quantities. Importantly, they do not meet the criteria to be placed into tier 1. Nevertheless, their impact as biothreat agents should not be underestimated. *Salmonella*, *Shigella*, and *Escherichia* species are substantial food safety threats. Similarly, *Vibrio cholera*, *Cryptosporidium parvum*, and various plant and microbial toxins can be dangerous and costly water safety threats. Although large-scale delivery of many hemorrhagic fever viruses and arboviruses is less likely, their release into the general population would certainly instill fear and panic. Furthermore, the ongoing induction of antimicrobial resistance suggests that even organisms not categorized as select agents can become pathogens of increasing concern.

Pandemic preparedness and bioterrorism readiness

The terrorist attacks of September 11, 2001, and the mailing of anthrax spores in October 2001 changed the way of life for all people worldwide, especially those in the United States. The 9/11 Commission Report referred to it as "a day of unprecedented shock and suffering," noting that "the nation was unprepared." Reflections offered at the 15th memorial anniversary of 9/11 rightly identified the numerous changes made in disaster planning and emergency preparedness

since 2001. Plans at the national, state, and local levels have been developed to address mass casualties, displaced individuals, long-term health issues, and loss or disruption of government response. Incident command systems have been established, written protocols have been developed, and interoperability exercises, drills, and cross-training have been performed to respond more effectively, using an “all hazards” preparedness model. The 2009 H1N1 influenza pandemic, the 2015 Texas Ebola cases, and the 2019 COVID-19 pandemic were good tests of U.S. preparedness. Fortunately, the highly communicable H1N1 virus was not highly virulent, and the imported cases of Ebola, which caused infection in two health care workers, did not escape containment. However, COVID-19 challenged the very core of diagnostic testing and clinical response. The unfortunate loss of frontline health care providers, nurses, and laboratorians resulting from SARS-CoV-2 suggests that the United States is far from ready for bioterrorism, let alone a global pandemic that was anticipated months before arriving in the United States. These events provided many valuable lessons.

Concluding thoughts

Regardless of the type of threat agent, release of a select agent into the general population will certainly challenge the best sentinel laboratory. Biosafety practices aside, the lack of familiarity with rare organisms to have first-hand experience with culturing, biochemical testing, and sensitivity results and techniques could result in delayed recognition of the potential risk. Additionally, a bioterrorism event would suggest large numbers of people seeking diagnosis and care, thus producing a large influx of patient specimens for analysis. This would certainly require significant resources in terms of laboratory media, reagents, primers, probes, technical and clerical time, as well as security. Sound biorisk management practices should be part of any laboratory response plan.

Furthermore, it must be remembered that a bioterrorism event is a crime. Patient specimens are evidence in that crime and as such must be cataloged, processed, and protected in case the evidence is used in a court of law. Another point is the psychological stress placed by a bioterrorist event on the general population and health care professionals. The medical laboratory scientist is already on the frontline of our battles in health care. Adding the additional stress of working with potential select agents introduces another dimension for which the laboratory scientist should be prepared.

Forensic microbiology

A newer field of study combines forensic science and microbiology. The area of forensic microbiology involves determining the cause of death and identifying those individuals who have committed crimes. Biocrimes and bioterror fall under the umbrella of forensic microbiology. This field of study includes the clinical microbiologists who identify infectious agents, public health officials, and law enforcement agents. In forensic microbiology, it is not sufficient to identify the genus and species of a bacterial agent; the microbial strain

or signature must also be determined. This is important to track the source of the agent in an outbreak. Microbial signatures are generally determined based on nucleic acid characteristics, sometimes termed *DNA fingerprinting*. The methods used include PCR assays, gene sequencing, and pulsed-field gel electrophoresis (see [Chapter 11](#)).

Recently, determination of the stable isotope ratio of atoms, such as carbon, nitrogen, oxygen, and hydrogen, has been used to determine microbial signatures. The media used to cultivate bacteria contain isotopes that will be incorporated into the bacteria as they grow. The isotope pattern might be unique to a geographic location, allowing scientists to not only determine if the bacteria came from the same source but also identify the location where they were grown.

Another role of forensic microbiology is determining the cause of death in sudden infant death syndrome (SIDS), defined as sudden unexpected death in presumably healthy infants younger than 1 year of age. SIDS is the leading cause of death in neonates in developed countries and is a multifactorial condition involving sleeping position, genetic and immunologic factors, and infections. An estimated 10% of SIDS cases are caused by undiagnosed infections. Several infectious agents, including Epstein-Barr virus, cytomegalovirus, respiratory syncytial virus, *Neisseria meningitidis*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*, have been linked to this syndrome. Determining an infectious cause is not always easy. Merely the detection or isolation of an infectious agent in postmortem tissue does not mean that the agent had a role in the death. It is possible that the bacteria simply colonized the patient before death and spread after death. Forensic microbiology can also play a role in ruling out shaken baby syndrome, which is characterized by unexplainable intracranial and retinal hemorrhages and acute encephalopathy. Staphylococcal septicemia and meningitis can produce similar clinical findings, and if detected postmortem, can exonerate individuals accused of homicide.

Forensic microbiology has been investigated as a way to help determine drowning as a cause of death. The diagnosis of drowning can be difficult and is often made by the exclusion of other causes. Forensic scientists have looked for microorganisms, such as diatoms, in the tissue of suspected drowning victims. Diatoms are single-celled organisms found in freshwater, saltwater, soil, air, and food. It is believed that their presence in postmortem tissue, such as the liver, bone marrow, and kidneys, proves the hematogenous spread of the organisms from the lungs from a beating heart before death. However, testing for diatoms is labor-intensive, and diatoms have been notably absent in cases of known drownings. Because of these drawbacks, forensic scientists have investigated the detection of fecal bacteria in postmortem tissue. Some bodies of water are contaminated with animal feces and contain bacteria colonizing the GI tract, such as *Escherichia coli* and *Enterococcus faecalis*. Testing the drowning medium as well as the postmortem tissue is required. If the same bacteria are found in the tissue as those in the drowning medium, it can be concluded that the likely cause of death was drowning. Recently, scientists have investigated using aquatic bacteria (bacterioplankton) in suspected drowning cases. These agents are more abundant and much smaller than diatoms, making it easier for them to enter the bloodstream and reach the viscera.

Aeromonas, *Vibrio*, and *Photobacterium* are the genera being studied. The bacterial genome can be detected using PCR or next-generation sequencing.

Determining time of death, or postmortem interval (PMI), is often critical information in an investigation into a suspicious death. PMI is classically determined based on changes in the body after death (e.g., body temperature, decomposition, rigor mortis, insect infestation) combined with information gathered from investigations by law enforcement agents. Recently, scientists have been investigating changes in the microbiome that occur after death to estimate the PMI. The postmortem microbiome can be divided into two components: the thanatomicrobiome (*thanatos*, Greek for “death”) and the epinecrotic microbiome (on the surface of decomposing remains). The thanatomicrobiome is composed of mainly bacteria and fungi present in the blood and internal organs, while the epinecrotic microbiome is composed of the microorganisms residing in or on the surface (e.g., superficial epithelial tissues, oral mucosal membranes). After death, because of the cessation of innate and adaptive immune responses, gut bacteria begin to spread to the surrounding tissues and organs and move along the circulatory and lymphatic systems, initiating the decomposition process. Typically, as decomposition progresses, microbial community diversity decreases, resulting in only a few genera predominating. There is a gradual shift from aerobic-based communities to communities based primarily on anaerobes. As more data are collected, it might be possible to develop a microbiome “calendar” with several time points that can match the bacteria detected from a cadaver to a specific time point.

POINTS TO REMEMBER

- Bioterrorism is the use (or threatened use) of biological agents to harm humans, animals, or crops to cause civil unrest. Biological warfare is the use of biological weapons to gain a military advantage.
- Many of the biological agents, both bacteria and viruses, used in bioterror are zoonotic.
- Many biological agents used in bioterror can also be isolated from patients with naturally occurring infections.
- Many infections caused by bioterror agents produce similar nonspecific symptoms in patients; therefore the laboratory scientist plays a key role in the diagnosis.
- Sentinel laboratories play a crucial role in the rapid detection and reporting of potential biological agents. As such, the laboratory scientist must be aware of the select agent rules, proper biosafety containment, and biosecurity and perform a biological risk assessment.
- The ASM provides information on minimal tests for the identification of potential bioterror agents for sentinel laboratories to use.
- Clinical microbiologists in sentinel laboratories should immediately notify their state public health laboratories when a potential biological agent cannot be ruled out and receive instructions and guidance on the chain of custody and shipping.
- The field of forensic microbiology includes the investigation of bioterror, biocrimes, unexpected deaths, and sometimes drownings.

LEARNING ASSESSMENT QUESTIONS

1. Which statement is correct regarding bioterrorism?
 - a. It only involves foodborne transmission.
 - b. It is the accidental release of viruses, bacteria, or other germs used to cause illness or death in people, animals, or plants.
 - c. It is the intentional release of viruses, bacteria, or other agents used to cause illness or death in people, animals, or plants to cause panic.
 - d. It is the release of viruses, bacteria, or other agents by the government to cause illness or death in people, animals, or plants.
2. Which of the following is (are) used to select an agent for bioterrorism?
 - a. Lethality
 - b. Ease of delivery
 - c. Ease of acquisition
 - d. All of the above
3. You might suspect the release of a bioterrorism agent if which of the following occurs?
 - a. Large numbers of people seek treatment at hospital emergency departments.
 - b. There are reports of unusual microorganisms being isolated from sick people.
 - c. There is a large die-off of animals in your area.
 - d. All of the above.
4. How are bioterrorism agents classified? (*Select all that apply.*)
 - a. UN 3373
 - b. Tier 1
 - c. Class 6.1
 - d. Category Y
5. Which of the following methods is used to identify agents of bioterrorism?
 - a. Culture
 - b. Biochemical analysis
 - c. Genetic sequencing
 - d. All of the above
6. Which of the following diseases is transmitted principally by fleas?
 - a. Plague
 - b. Tularemia
 - c. Anthrax
 - d. Rocky Mountain spotted fever
7. Which organism produces a toxin used as a bioterrorism agent?
 - a. *F. tularensis*
 - b. *Y. pestis*
 - c. *C. botulinum*
 - d. *B. anthracis*
8. Depending on the agent, all incidents involving select agents should be reported to local and state public health authorities as well as the:
 - a. Central Intelligence Agency
 - b. U.S. Department of Homeland Security
 - c. U.S. Centers for Disease Control and Prevention and the U.S. Department of Agriculture
 - d. U.S. Department of Justice and the U.S. Postal Service
9. Biosafety level designation would change from _____ to _____ when moving from diagnosing tuberculosis in specimens using direct staining of smears to culturing mycobacteria.
 - a. BSL-2 to BSL-3
 - b. BSL-3 to BSL-4

- c. BSL-2 to BSL-4
- d. It would not change.
10. The biosafety level of a laboratory is defined by which of the following?
 - a. Risk group and procedures of the agent used in the laboratory
 - b. Biochemical virulence factors of the agent used in the laboratory
 - c. Risk group and risk assessment of the agent used in the laboratory
 - d. Gram stain and microscopy of the most virulent agent used in the laboratory
11. Shaken baby syndrome can be confused with which of the following?
 - a. Sudden infant death syndrome
 - b. Bacterial septicemia and meningitis
 - c. Variola virus infection
 - d. Tularemia
12. The finding of diatoms in a cadaver found in a body of water is suggestive of which of the following?
 - a. Stabbing
 - b. Encephalitis
 - c. Strangulation
 - d. Drowning
13. Many years ago, *Bacillus anthracis* and variola major virus were classified as BSL-2 agents. Those classifications have been modified to fall under higher BSLs. Why was a change necessary?
14. What important roles do reference laboratories perform within the LRN?
15. Which unique pathogenic features distinguish tier 1 agents from those in the non-tier 1 group?
16. For each of the following organisms, what specific identification characteristics (e.g., Gram stain morphology and biochemical test results) must be met before a sentinel laboratory must contact an LRN reference laboratory to submit a sample?
 - a. *Bacillus anthracis*
 - b. *Yersinia pestis*
 - c. *Francisella tularensis*
 - d. *Burkholderia* spp.
17. What are the recommended clinical specimens to submit for patients potentially exposed to the following?
 - a. Ebola virus or Marburg virus
 - b. *Clostridium botulinum* toxin
 - c. Inhalational anthrax
 - d. Variola virus

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the proposed origin of biofilms, in a historic perspective, as a means of microbial survival.
2. Define *biofilm*.
3. Compare the planktonic phenotype with the sessile phenotype.
4. Describe the interaction of multiple cells in a community.
5. Describe the five stages of biofilm formation.
6. Discuss the architecture of biofilms.

7. Describe the potential virulence mechanisms of biofilms.
8. Discuss the role of biofilm formation in periodontal disease.
9. Explain the role of indwelling medical devices and the pathogenesis associated with biofilms.
10. Discuss the consequence of biofilms for the clinical laboratory, particularly false-negative cultures, viable but nonculturable bacteria, low colony counts, inappropriate specimen collection, and loss of susceptibility to antimicrobial agents.
11. Evaluate the various biofilm interventions and their limitations.
12. Analyze laboratory methods that may be used to study biofilms.
13. Describe how bacterial cells communicate.

KEY TERMS

Biofilm

Biofouling

Exopolysaccharide (EPS)

Persister cell

Pheromone

Planktonic

Quorum sensing (QS)

Quorum-sensing inhibitor (QSI)

Sessile

Case in point

An 83-year-old female patient was admitted to the hospital after developing a fever and having a hypotensive episode while in residence at a nursing home. The patient had a clinical history of rheumatoid arthritis, hypertension, atrioventricular block, gastroesophageal reflux disease, deep vein thrombosis with pulmonary embolism, and depression. The patient also had a history of recurrent prosthetic left knee joint infections after total knee arthroplasty 2 years earlier. A vancomycin-resistant enterococcus (VRE), *Enterococcus faecium*, was the predominant organism isolated in synovial fluid from her knee. The patient was given multiple antimicrobial regimens with numerous revisions. The course of her illness was complicated by pancytopenia, most likely caused by injury to the bone marrow, possibly from a drug reaction. At this admission, blood and synovial

fluid cultures were collected. The patient was given antimicrobial therapy and supportive care, but her condition worsened, and “comfort measures only” were instituted. When the patient died, an autopsy was requested by the family. The final pathologic diagnoses were as follows:

- Nonhealing chronic wound infection caused by VRE associated with prosthetic left knee joint and clinical history of sepsis
- Pulmonary edema and pleural and peritoneal effusions
- Pulmonary vascular calcifications and cardiomegaly

Issues to consider

After reading the patient's case history, consider:

- The role and significance of biofilms in infectious diseases
- The difficulty of successfully treating infections involving biofilms
- The consequences of untreated biofilm diseases
- Whether laboratory standard practices should be altered to meet the challenges presented by biofilm-associated infections

Biofilms are three-dimensional communities of microorganisms attached to a solid surface; the surface can be abiotic (nonliving) or living tissue. Organisms in a biofilm are specialized and have a great deal of genetic energy. Given the selective pressures of certain environments, notably aquatic systems, biofilms are the preferred method of growth. Their unique structure, which evolves over time, allows the development of a cohesive, robust community of cells, with interspecies communication driven by the principle of survival. Microorganisms, prokaryotic or eukaryotic, have the potential to live in one of two phenotypes: sessile or planktonic. The **sessile** phenotype results from attachment and usually develops into a multispecies biofilm that has unique characteristics, making it similar in many ways to hydrated polymers. **Planktonic** forms are free-floating microorganisms.

Biofilms can be simple monospecies or complex cobiofilms. Cobiofilms, or multispecies biofilms, predominate in most environmental sites (Fig. 31.1). Biofilms can form on a variety of surfaces, such as on ships' hulls and rocks in rivers and streams. Biofilms that occur inside pipes carrying water

Fig. 31.1 Natural biofilm on a metal surface. This is a scanning electron micrograph of a native biofilm that developed on a mild steel surface in an 8-week period in an industrial water system ($\times 20,000$). (Courtesy Rodney Donlan and Donald Gibbon, from the American Society for Microbiology MicrobeLibrary.)

for the manufacture of drugs make it unsafe because of the presence of the organisms and toxins such as endotoxins that can induce septic shock in individuals receiving the drugs. Biofilms inside pipes that carry water can make the water not potable. The process of biofilms forming on surfaces of pipes carrying potable water is referred to as **biofouling**.

Cobiofilms of bacteria and fungi have been found in ventilator systems of airplanes, ice machines in restaurants and bars, and mines, in which unique configurations have been found that result from the leeching process, creating stress on the inanimate surface. Biofilms that involve mastitis in farm animals affect agriculture, and biofilms in barrels can cause wine to spoil, affecting the wine industry. Cobiofilms of *Pseudomonas aeruginosa* and *Burkholderia cepacia* are associated with serious lung infections in patients with cystic fibrosis (CF). Monospecies biofilms are associated with a variety of infections. Medically important biofilms are produced by bacteria such as *P. aeruginosa*, *P. fluorescens*, *S. aureus*, and *S. epidermidis*.

It is important for clinical microbiologists to become familiar with the role biofilms play in human disease. As people live longer or are in a prolonged debilitated state of health and/or undergo invasive procedures, they are more prone to infections by opportunistic pathogens and the development of biofilms. Recently, the challenges that biofilms present to the clinical microbiology laboratory have been recognized. These include problems in performing susceptibility testing, interpreting the clinical significance of susceptibility test results, recovery of viable but nonculturable organisms in a mixed-species biofilm, and the recognition that biofilms transform from gram-positive to gram-negative in an environment that is difficult to duplicate. This chapter presents an overview of biofilm properties and composition and discusses the consequences and challenges associated with biofilms that the medical laboratory scientist must confront. Diseases associated with biofilms are presented, and potential interventions are introduced.

Microbial biofilms defined

Several definitions exist for the term *biofilm*. These have evolved over time as our understanding of the forces and features of biofilms has progressed. However, the definition in Box 31.1 seems to endure and puts into perspective the concept of developmental biology and the uniqueness and cooperation required among organisms within the biofilm. One such definition recognizes the components and imperative ingredients that characterize this multiorganism cooperative population. According to the definition, microbially derived sessile communities are characterized by cells irreversibly attached to a

BOX 31.1 Biofilm definition

A biofilm is a primitive developmental biological system in which spatial organization of the cells within the matrix optimizes the use of available nutritional resources. An immobilized enzyme system is formed in which the milieu and enzyme activities are constantly changing and evolving to an appropriate steady state. The steady state can be radically altered by applying physical factors, such as high shear force.

substratum, or interfaced to each other, embedded in a matrix of an extracellular polymeric substance that produce and exhibit an altered phenotype with respect to growth rate and gene transcription.

Microbial biofilms (biofilm phenotype) are as common as planktonic microorganisms (planktonic phenotype). Almost any liquid environment in which organisms are subject to shear forces and nutrition alteration selects for upregulation—that is, increased expression of genes consistent with the biofilm phenotype. Planktonic phenotype and biofilm phenotype cells can have the same genetic potential but express a different phenotype. Given the appropriate environmental selective pressures, a significant number of bacteria will preferentially develop a biofilm phenotype. It is important to recognize that the two phenotypes are not mutually exclusive, but that the ratio of the planktonic phenotype to the biofilm phenotype can be a predictor of associated disease. Biofilms are a universal mechanism for survival, horizontal gene transfer, and growth as well as a probable ancestor of the planktonic free-floating microorganisms. The planktonic phenotype is genetically expensive, with sophisticated chemotactic and mobility mechanisms that may have developed after the biofilm phenotype. The primary purpose of the planktonic phenotype is dissemination and colonization of new habitats.

There is growing evidence that the biofilm was the origin of survival and necessary for communication among microbes. Approximately 3.4 billion years ago, biofilms allowed microbes to survive, grow, and adapt in a hostile environment, including extreme pH and temperature and lack of water. As the Earth cooled and moved toward a multispecies adaptation with less environmental pressure, organisms were able to develop the ability to transfer to different ecologic niches and live outside communities. Hence, the postbiofilm planktonic phenotype evolved, which had a reduced need for communities for survival.

Biofilms: community of cells

Although certain constituents are common to all biofilms, the contribution of the host relative to the microorganisms,

such as immunologic components and the physical location, has an antibody influence on biofilm structure. Several key environmental and cultural characteristics affect the selection of multispecies biofilm inhabitants (Fig. 31.2). These features include (1) species attachment efficiency, (2) genotypic factors, (3) cyclic stage of biofilm, (4) substrata, (5) nutritional resources, (6) mechanical factors and shear forces, (7) physicochemical environment, and (8) anti-infective hostile pressure forces. Of these, the four most important are organism attachment efficiency, nutritional resources, substrata, and environmental shear stress or force. Shear stress, probably the most important characteristic, affects the physical morphology and dynamic behavior of the biofilm. The steady-state kinetics of the organisms within the biofilm can be radically altered by physical factors such as high shear, and the shear rate will determine the rate of erosion of cells and of the matrix from the biofilm.

As a biofilm forms, streamers of cells extend from the surface. These cells can break off and establish new biofilms downstream. Not all microorganisms change with a high efficiency of upregulation between the planktonic and biofilm phenotypes. It is no coincidence that coagulase-negative staphylococci, *P. aeruginosa*, and *Candida albicans* are some of the most efficient microbes prone to upregulation when selective pressures magnify the need for survival in a biofilm community. These microorganisms are also important human pathogens. Both prokaryotes and eukaryotes are important in biofilm-associated diseases. In particular, a cobiofilm of *Candida* and pseudomonad species is very difficult to eliminate because of its drug resistance. A cobiofilm increases in robustness and stability with maturity and the number of organisms within the community.

Stages in biofilm formation

Biofilm formation progresses through well-regulated steps that include attachment of cells to a substrate, growth and aggregation of cells into microcolonies, and maturation and maintenance of architecture. During the process, many

Fig. 31.2 Environmental and cultural factors that affect biofilm development.

species of microorganisms progress through multiple developmental stages. There is a five-stage universal growth cycle of a biofilm with common characteristics independent of the phenotype of the organism.

Stage I is the attachment phase, which can take only seconds to start and is likely induced by environmental signals. These signals differ by organism but include changes in nutrients and nutrient concentrations; pH, temperature, oxygen, and iron concentration; and osmolality. Even though biofilms can form on any surface, rough surfaces are more susceptible to biofilm formation. This is likely because of the reduction of shear forces and increased surface area. Biofilms also tend to form more readily on hydrophobic material, such as Teflon and other plastics (polymers), than on glass and metals. [Table 31.1](#) lists some key factors in biofilm formation. The initial binding in stage I is reversible as some cells detach from the substratum. Binding to a surface is mediated by several adhesion molecules and pili. One example is polysaccharide intercellular adhesion, which is produced by enzymes encoded by the gene locus *ica* found in *S. aureus* and *S. epidermidis*. In *Escherichia coli*, there are genes that encode a similar polymer associated with adhesion, designated *pga*, and they share sequence similarity with the staphylococcal genes *ica*. It has been observed that exposure to subinhibitory concentrations of various antimicrobial agents activate the expression of *ica*.

After attachment, the cells undergo changes in gene expression that lead to existence on a solid surface. It has been shown with *C. albicans* that switching from yeast forms to hyphal growth is important in biofilm development. During stage I, bacterial cells exhibit a logarithmic growth rate. Stage II is characterized as irreversible binding and begins minutes after stage I. During stage II, cell aggregates are formed, and motility is decreased. Toward the end of this stage, **exopolysaccharide** (EPS) is produced, which can trap nutrients and planktonic bacteria. In staphylococci and enterococci, iron deprivation and osmotic stress induce the expression of genes encoding proteins that synthesize EPS. It has been shown that alginate, an EPS, is increased threefold to fivefold in *P. aeruginosa* after attachment to a solid surface compared with planktonic cells.

When cell aggregates become progressively layered, with a thickness greater than 10 μm , the biofilm is in stage III. This stage is also referred to as *maturation 1*. When biofilms reach their ultimate thickness, generally greater than 100 μm , this is referred to as stage IV or *maturation 2*. It takes a biofilm several days to reach this stage. Some of the cell aggregates are displaced from the substratum but remain trapped in the biofilm EPS. During stage V, cell dispersion is noted. Some of the bacteria develop the planktonic phenotype and leave the biofilm. Stage V begins several days after stage IV.

Cycling of stage I to stage V is based on the organism pool and timing of the growth characterization of the individual members. The formation of a biofilm has been compared with cell differentiation of a multicellular organism. One reason for this comparison is that microorganisms in a biofilm express great variability in metabolic activities. A biofilm is a dynamic system, containing many species of bacteria with different characteristics. It is also recognized that there is a constant assessment of the need to remain within the cycle, attached or free-floating, and, again, neither is mutually exclusive. Certain organisms, however, have evolved a much more efficient means of maintaining one phenotype or the other.

The organization of biofilms may take several forms, but it is important to recognize that a nonuniform spatial pattern and nonuniform susceptibility with physiologic heterogeneity equals survival in a harsh environment, such as one containing antimicrobial agents. **Persister cells**, essentially metabolically inert microorganisms analogous to bacterial spores, are present in all biofilms and bacterial populations. Persister cells are hypothesized to have disabled programmed cell death, or apoptosis. These cells have the greatest potential for maintenance of the gene pool and resistance to environmental stress, including antimicrobial agents.

Much of the development and structural integrity of the biofilm depends on **quorum sensing** (QS) by QS autoinducers. QS is the ability to use extracellular molecules, **pheromones**, for enhanced communication among bacteria not only of the same genera and species but also among bacteria of different genera and species. The ability of bacteria to communicate among themselves shows a behavior analogous to what occurs among animals and people. The most striking element of QS in gram-negative organisms is the highly conserved set of three-component regulatory networks used by these organisms to efficiently regulate a wide variety of bacterial density-dependent activities, such as metabolism, virulence, chemotaxis, and notably, biofilm production and maturation.

The viability of the biofilm community depends on stress response genes and cell signaling from the cells via QS through biochemicals. QS is essential for biofilm formation, triggering expression of some genes and downregulation (silencing or reducing expression) of others. Pheromones are different for gram-positive and gram-negative bacteria. Gram-negative bacteria use low-molecular-weight homoserine molecules, such as *N*-acyl homoserine lactone, whereas gram-positive bacteria use oligopeptides or proteins. The role of QS for different organisms mechanistically in a biofilm community remains to be understood. Physical contact, or cell aggregation, can also provide signals that are important in biofilm formation. Challenges in the study of biofilms include:

1. Which parameters of a biofilm community influence the onset of QS and subsequent patterns of gene expression?
2. What are the functional challenges of QS?
3. Does induction of QS influence the pathogenic potential of biofilm communities?
4. Does induction of QS alter the antimicrobial tolerance of a biofilm community?
5. Are there organisms in a biofilm community that eliminate or reduce signal transfer among organisms?
6. Does interspecies signaling occur in mixed-species systems, and what triggers this signaling?

Table 31.1 Important variables in cell attachment and biofilm formation

Properties of substratum	Properties of surrounding fluid	Properties of the cell
Texture or roughness	Flow velocity	Cell surface
Hydrophobicity	pH	hydrophobicity
Conditioning film	Temperature	Fimbriae
	Cations	Flagella
	Available nutrients	Adhesion molecules

Not only does QS occur among bacteria, but it has now become evident that host tissue can exploit bacterial QS to influence commensal bacteria. In addition, research suggests that serotonin, a neurotransmitter responsible for mood in the brain and motility in the gut, can also act as a bacterial signaling molecule for pathogenic bacteria. In an animal model, it was shown that serotonin enhanced the virulence of *P. aeruginosa*.

Architecture of biofilms

It is important to recognize the interplay of biofilm and planktonic phenotypes and the three-dimensional architecture of the biofilm as being universal, whether the biofilms are in animals, agricultural environments, or industrial settings. Biofilms are composed of stalks of mushroom-shaped microcolonies attached to the substratum and surrounded by EPS. The biofilm matrix contains EPS, proteins, and DNA; EPS constitutes 50% to 90% of the organic carbon in the matrix. Biofilms are hydrated, with fluid-filled channels running throughout. The fluid-filled channels facilitate the exchange of nutrients and carry away waste products. In addition, motile microorganisms can be found in the aqueous portion of a biofilm. [Table 31.2](#) lists some commonly found constituents of biofilms.

The three-dimensional architecture of the mature biofilm often has three layers. The outermost layer is exposed to the highest concentration of nutrients and oxygen. It contains the most active organisms, which primarily resemble the structure and activity of their planktonic counterparts. These organisms are generally closely aligned, with selective pressures. Even though they are also part of the EPS, the organisms can slough off and initiate biofilm formation downstream. The second layer of the biofilm architecture is an intermediate level. Organisms in this layer downregulate their metabolic activity somewhat, but they clearly have the capacity to use nutrients and exchange genes and have the potential for multiple drug resistance. This spatial arrangement, physiologic heterogeneity, and nonuniformity are based on the proximity of microorganisms aligning next to one another. They benefit from that alignment, and it is not by chance. The innermost layer of cells is attached to the substratum and represents the earliest part of the biofilm. These microorganisms are the least metabolically active, and this is where most persister cells are located. Generally, the innermost layer represents the inheritance for future populations that transfer genes laterally.

Table 31.2 Components of biofilms	
Component	Percentage of matrix
Water	≤97%
Microbial cells	2%–5%; many species
Exopolysaccharide	1%–2%
Proteins	<1%–2%
DNA and RNA	<1%–2%

Biofilm properties

Biofilm phenotypes cannot be defined by traditional principles of microbiology. Cell behavior in response to stress is much more than a group of microbes attached to a surface. In fact, the properties of a biofilm resemble the properties of organic polymers. Two key properties of a biofilm are attributable to their hydrated polymer gel-like material. First, biofilms exhibit viscoelasticity (i.e., viscous and elastic properties). The consequence of this viscoelastic property is magnified in the time-dependent response of biofilms. In short periods, biofilms absorb increased shear by behaving elastically. In contrast, for long periods, shear is dissipated through viscous flow by a streamlining of the structure to reduce drag.

This viscoelastic property can be measured by using principles of rheology, meaning that everything flows. The Greek philosopher Heraclitus (540–480 BC) of Ephesus said: “Everything flows and nothing abides; everything gives way and nothing stays fixed.” In a more practical sense, will it flow, or will it fracture? The outcome is determined by the applied forces. This also explains the phenomenon of creeping, or rolling, that allows a multispecies biofilm to move like lava flow when attached to an inanimate or abiotic surface. There is no detachment; rather, it is the movement of a protective community down a surface, as defined by viscoelastic properties of a material-like substance. This is of major concern when addressing, for example, movements of biofilms within the lumen of an endotracheal tube or a central catheter line.

Second, not only do biofilms share properties of organic polymers, but they also have many properties common to a neoplasia, another cell community. A neoplasia is a eukaryotic irreversible genotype. In contrast, members of a biofilm have reversible phenotypes, and they are more often prokaryotes. However, given these differences, several features are shared by a neoplasia and a biofilm to some degree. Common to both are cycling or staging, metastasis, loss of contact inhibition, and cell-to-cell signaling. Similarities can also be observed in the three-dimensional architecture, heterogeneity, and virulence phenotype. The sharing of characteristics between a neoplasia and a biofilm highlights the fact that biofilms are different from their free-floating counterparts.

Mechanisms of pathogenicity

A great deal has been learned about the structure, function, and properties of biofilms. The mechanisms of pathogenicity, on the other hand, are a different matter.

- Do biofilms contribute to infectious disease?
- If so, what are the mechanisms of pathogenicity?
- Are some biofilms more pathogenic than others?

Some observations appear to provide evidence of the significance of biofilms in the mechanisms of disease. [Box 31.2](#) lists several potential pathogenic mechanisms concerning biofilms and disease. In the environment and in patients, biofilms are the most advantageous method of growth for most microorganisms. Biofilms originate because of selective

BOX 31.2 Biofilm pathogenicity and disease

- Allows attachment to a solid surface
- "Division of labor" increases metabolic efficiency of the community
- Evades host defenses such as phagocytosis and antibodies
- Produces a high density of microorganisms
- Horizontal gene transfer can result in more virulent strains of microorganisms
- Produces a large concentration of toxins
- Protects against antimicrobial agents
- Can aid penetration of host tissue
- Detachment of microbial aggregates transmits microorganisms to other body sites

pressures in an environment in which survival can be difficult, such as the presence of host defenses and antimicrobial agents. Transitioning from acute to chronic infections is frequently associated with biofilm formation.

Case check 31.1

An aggregation substance protein produced by *Enterococcus faecalis* stimulates the production of a biofilm. The protein induces aggregation formation between *E. faecalis* cells. This protein can also facilitate adherence to host tissue. The patient in the Case in Point had a chronic VRE infection associated with a prosthetic left knee joint. It is likely that biofilm formation was involved.

Role of biofilms in attachment

Colonization is often a critical first step in the development of an infectious disease, and biofilms may be an important mechanism of attachment to host tissue and indwelling medical devices (IMDs). Intravascular catheters, urinary catheters, pacemakers, heart valves, stents, and orthopedic implants are just a few examples of IMDs. Initial colonization involves bacterial adhesions such as surface proteins (e.g., teichoic acid, lipoteichoic acid) and pili. Motility is also important for initial colonization. However, after bacteria adhere to a surface and biofilm construction begins, changes in gene expression result in the suppression of flagella and increased expression of adhesion molecules. However, once a biofilm is established, adhesion mechanisms are no longer needed.

Benefit of biofilms for metabolism

Biofilms allow members of the microbial community to withstand the shear forces of blood and urine flow, presumably keeping the microorganisms in a nutrient-rich environment. It was demonstrated with certain organisms, such as the pseudomonads, *E. coli*, and *Vibrio cholerae*, that the presence of an abundant usable carbon source (e.g., glucose) stimulates the production of EPS. The EPS can trap more microorganisms and can serve as a glucose storage mechanism at times when carbohydrates are plentiful. As nutrients in the surrounding environment become scarce, gene expression changes, and some bacteria in the biofilm detach and become planktonic.

Because of the extreme variability in available nutrients, pH, and oxygen concentration in a large complex biofilm, there is great heterogeneity in the metabolic activity of microorganisms in the community. Even in monospecies biofilms, metabolic requirements and activities differ. This variability may result in a so-called *division of labor*, whereby the metabolic efficiency of the microbial population is increased. Sharing of metabolic by-products is the basis of a beneficial symbiotic relationship. It has been proposed that bacteria living in a biofilm can exhibit mutually beneficial behavior. Evidence indicates that bacteria can undergo programmed cell death. Death of some cells in the community could relieve the metabolic load by releasing nutrients for nearby cells. This would help the biofilm to survive. One of the major benefits of the biofilm configuration is its ability to produce many organisms per unit mass. Generally, in broth cultures, it is difficult to obtain more than 10^8 cells/mL, but with configuration and upregulation of a biofilm phenotype, microorganisms can reach concentrations of 10^{12} cells/mL or higher.

Biofilms as a defense mechanism

Biofilms can afford protection from host defenses, including oxygen-reactive molecules, antimicrobial proteins like antibodies, antimicrobial drugs, and phagocytosis. In addition, biofilms protect against pH changes and nutrient deprivation. A major benefit of the biofilm to microorganisms is its interference with immune function, particularly the activity of white blood cells. The biofilm provides a physical barrier that prevents phagocytic cells, such as polymorphonuclear (PMN) cells, from penetrating and phagocytizing the bacteria. When confronting a biofilm, PMN cells will degranulate and cause damage to nearby host tissue. In periodontal disease, the consequence of interrupted white blood cell function is the production of large quantities of collagenase of human origin that causes deterioration of support bone. In addition, biofilms can hide microbial antigens, inhibiting an immune response by preventing antibody formation, and even if antibodies are formed, they block interaction with bacterial antigens. Antibodies cannot diffuse through a biofilm, but immune complexes can form on the biofilm surface and nearby tissue, producing inflammation.

How a biofilm provides protection to its members is not completely known. Possibly, sticky EPS provides a physical barrier to penetration by phagocytic cells and antimicrobial molecules. Also, the heterogeneity of microbial metabolic activity may play a role. It is known that slow-growing organisms are more resistant to antimicrobial agents. This seems counterintuitive because one argument for forming a biofilm is the presence of a nutrient-rich environment; however, those microorganisms living near the substratum exist in a nutrient-poor environment and therefore grow slowly. The upregulation of the biofilm phenotype by microorganisms has the potential to outcompete normal biota. This is also particularly appropriate as bacteria transition from acute infections to chronic infections, more likely associated with the biofilm phenotype and the coaggregates of multispecies biofilms. The early bacterial population during an acute infection will be exceeded later in the course of the disease, when the organisms reach a biofilm configuration. The microbial

population is also often susceptible to antimicrobial agents early in the infections, as determined by genotyping, but becomes much more resistant as the population shifts to a biofilm phenotype. Removal of the selective pressure is critical in shifting the ratio of biofilm phenotype to planktonic phenotype back to the planktonic phenotype in the nondisease state.

Biofilms afford bacteria the opportunity to become tolerant to antimicrobial agents. Bacterial tolerance is defined as resistance to antimicrobial agents in bacteria residing in a biofilm as a result of existing genes. Susceptibility is restored when the bacteria leave the biofilm. It is critical to remember that the classic mechanisms of genetically encoded bacterial resistance can also operate in bacterial biofilms. Multidrug efflux pumps, antibiotic-modifying enzymes, and bacterial modifications are all viable modes of resistance for biofilms. However, these classic resistance mechanisms do not explain the resistance observed in bacteria that do not possess known antimicrobial-resistance genes.

Several hypotheses may explain biofilm resistance to antimicrobial agents: (1) inability of an antimicrobial compound to penetrate all areas of the biofilm; (2) altered areas of metabolic activity of the bacteria or reduced growth rate, rendering antimicrobial agents such as penicillin, which can inhibit the growth of only actively growing bacteria, ineffective; (3) persister cells, which are dormant, nondividing cells; and (4) differential gene expression within the biofilm community, which may allow certain bacteria to protect other bacteria by producing needed nutrients, compounds that inactivate antimicrobials (e.g., penicillinase), or other necessary compounds that regulate the physiology of the biofilm community. Persister cells, phenotypic variants of the wild type, will neither grow nor die in the presence of a drug. Despite their small number (1%) in the biofilm, persister cells are important in pathogenesis. During aggressive antimicrobial treatment, persister cells will survive. When the antimicrobial agent is removed, the persister cells can then give rise to normally growing cells. These cells may be responsible for some recurrent infections.

Gene transfer and expression

A biofilm is an optimal environment for the horizontal transfer of genetic material (i.e., DNA). The microorganisms live in close proximity; this facilitates the uptake of DNA by transformation and conjugation. Plasmids, for example, are expensive for cells to maintain unless they offer a selective advantage. If a plasmid is lost by one cell or DNA is released from a cell because of lysis, a nearby cell may take it up, a process termed *transformation*. The horizontal gene transfer can lead to the spread of antimicrobial resistance within the community.

Upregulation to the biofilm phenotype has been associated with the clustering of genes associated with virulence. Some studies have indicated that the biofilm is a virulence factor and should be regarded as a means whereby a disease process is enhanced. Endotoxin and the production of extracellular enzymes by the community are controversial, but there is no question that enzymatic activity for certain cohabitants is increased and that there is no universal growth of the biofilm on an inanimate surface.

Disaggregation

Disaggregation or detachment of aggregates clearly has the potential of transmitting already upregulated resistant aggregates of microorganisms to other body sites. Like cancer metastasis, this is most significant when aggregates spread via the bloodstream. Disaggregation provides the microorganisms with an opportunity to reach almost any body site. Important to disaggregation is the resulting planktonic phenotype to biofilm phenotype ratio. As the ratio increases, the risk of the microorganisms spreading increases, leading to increased risk of more serious disease. There is some evidence, particularly in ventilator-associated pneumonia, that this ratio is a direct reflection of the disease process.

Case check 31.2

Despite antimicrobial therapy, the patient in the Case in Point experienced chronic VRE infection and septicemia. The biofilm produced on the prosthetic left knee joint afforded the bacteria protection from the host's defenses and antimicrobial therapy. The sepsis likely originated from disaggregated cells dislodged from the biofilm.

Diseases associated with biofilms

Medically, the primary location of biofilms is on IMDs, but they also exist in human tissue. An estimated 80% of all human infections are attributed to biofilms. They have been linked to vaginitis, colitis, gingivitis, conjunctivitis, urethritis, highly persistent wound infections, middle ear infections, and other infections. Biofilms may be one of the leading causes for a shift from acute-phase diseases to chronic and recurrent diseases. Hence, as we transition to an older population with more chronic infections and IMDs, it is important that the laboratory scientist consider this population and associated biofilm diseases. The list of human diseases associated with biofilms has grown significantly in the past several years and involves more than 30 bacteria and yeasts. [Table 31.3](#) lists several medical or dental biofilm-associated conditions. Diseases associated with biofilms include rhinosinusitis and soft tissue disease, particularly that of dystrophic epidermolysis bullosa. Clinical studies have recognized that nontuberculous mycobacteria can form biofilms on the human cornea, resulting in vision loss. The spirochete *Borrelia burgdorferi*, the causative agent of Lyme borreliosis (disease), forms biofilms that enhance its pathogenicity. It is possible that biofilm formation contributes to the chronic nature of Lyme disease. During chronic Lyme disease, the bacteria become more tolerant to antimicrobial therapy, and scientists have demonstrated the presence of persister cells in this situation. In almost all cases of chronic infections, the biofilm plays a key role in helping microorganisms survive or spread within the host.

Dental biofilms

Dental biofilms, more commonly called *plaque*, are probably the most studied natural human biofilm. The microorganisms

Table 31.3 Partial list of human infections involving biofilms

Infection or disease	Common bacterial species
Bacterial vaginosis	<i>Gardnerella vaginalis</i> , <i>Atopobium vaginae</i> , and other species
Biliary tract infections	Enteric bacteria
Cystic fibrosis	<i>Pseudomonas aeruginosa</i>
Dental caries	Various species
Endometritis, chronic	<i>Enterococcus faecalis</i> , <i>E. coli</i> , <i>G. vaginalis</i> , and other species
Infectious kidney stones	Gram-negative bacilli
Lyme disease	<i>Borrelia burgdorferi</i>
Musculoskeletal infections	Gram-positive cocci
Native valve endocarditis	Viridans group streptococci, staphylococci, and enterococci
Necrotizing fasciitis	Group A streptococci
Osteomyelitis	Various species
Otitis media	Nontypeable <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Moraxella catarrhalis</i>
Periodontal disease	Various species
Rhinosinusitis, chronic	<i>Staphylococcus aureus</i>
Typhoid fever, chronic	<i>Salmonella</i> Typhi
Wounds	Various species
Infections associated with foreign-body material	
Contact lenses	<i>Pseudomonas aeruginosa</i> , gram-positive cocci
Sutures	Staphylococci
Artificial heart valves	Staphylococci
Vascular grafts	Gram-positive cocci
Arteriovenous shunts	Gram-positive cocci
Endovascular catheter infections	Staphylococci
Peritoneal dialysis peritonitis	Various species
Urinary catheter infections	<i>Escherichia coli</i> , gram-negative bacilli
Intrauterine devices	<i>Actinomyces israelii</i> and other species
Penile prostheses	Staphylococci
Orthopedic prostheses	Staphylococci

*Biofilm formation in the gallbladder.

making up a dental biofilm are considered normal biota of the oral cavity. Plaque can lead to caries (dental cavities); gingivitis, a mild and reversible form of periodontal disease; and periodontitis, inflammation of deep tissue below the gum surface that can result in tooth loss. In addition, epidemiologic studies have linked dental plaque to cardiovascular disease. The rate of cardiovascular disease is 25% to 50% higher in patients with periodontitis than in healthy individuals. Atherosclerosis of coronary arteries begins as an inflammatory process involving the endothelial cells in the blood vessel wall. Macrophages, T cells and B cells, and mast cells accumulate.

Oral bacteria can access the bloodstream during gingivitis and colonize the coronary plaque, contributing to atherosclerosis by stimulation of an innate immune response. Damage to the periodontal tissue by the oral plaque bacteria can lead to release into the bloodstream of numerous cytokines (e.g., tumor necrosis factor alpha, interleukin-1, cathelicidin, and C-reactive protein) that might contribute to the atherosclerotic process in the coronary arteries. In addition, poor oral hygiene and gum disease can allow oral microbiota to reach the bloodstream. Normal oral microbiota associated with dental plaque, such as *Aggregatibacter actinomycetemcomitans*, *Eikenella corrodens*, *Streptococcus* spp., *Capnocytophaga*, *Neisseria*, and *Lactobacillus*, have been linked to infectious endocarditis.

Development of dental biofilms follows a sequence of events and involves hundreds of bacterial species. After a dental cleaning at the dentist's office, tooth enamel becomes coated with a variety of proteins and glycoproteins of host origin. This coating develops almost immediately and is referred to as the *acquired pellicle*. After pellicle formation, the primary colonizers, first streptococci (particularly the sanguinis-group streptococci) and later actinomycetes, colonize the surface of the teeth. Typical bacterial adhesion molecules and pili play a role in attachment to the pellicle. The bacteria can remain attached, despite shearing forces of saliva and tongue movement.

The bacteria on the pellicle form cell-to-cell interactions (aggregates or coadhesions), with the same species and with different species. The sessile organisms undergo cell-to-cell communication via QS, initiating changes in gene expression. Notably, several streptococci, including *Streptococcus mutans* and related organisms, begin to synthesize insoluble glucan polymers used in the production of a glycocalyx, an EPS. Bacteria from several species can bind to glucan via glucan-binding proteins. Bridge bacteria, including members of the genus *Fusobacterium*, form aggregates with the primary colonizers. The bridge bacteria cannot bind to the pellicle but can bind to the primary colonizers. The primary colonizers cannot directly form aggregates with the late colonizers. The late colonizers forming aggregates with the fusobacteria include *Streptococcus salivarius*, propionibacteria, *Prevotella*, *Veillonella*, and *Selenomonas flueggei*. At this point, the biofilm consists primarily of nonpathogens. However, in the presence of dietary sucrose and other carbohydrates, acids are produced via fermentation. The production of organic acids on the tooth surface can result in demineralization of the tooth enamel and, over time, caries.

At the base of the tooth between the tooth and gingiva (gum) is a crevice called a *sulcus*. The plaque can extend into this space and is referred to as *subgingival plaque*. In immunocompetent individuals with good oral hygiene, the plaque remains composed primarily of gram-positive bacteria. This condition is not generally associated with disease because of a balance between host defenses and bacterial growth. If the subgingival plaque is allowed to remain undisturbed for several days, the microbiota changes and becomes composed mainly of anaerobic and facultative anaerobic, gram-negative bacilli and spirochetes.

The last colonizers of the biofilm are considered pathogenic because of their role in periodontal disease. The most important pathogens include *Porphyromonas gingivalis*, *Bacteroides forsythia*, *Aggregatibacter actinomycetemcomitans*,

and the spirochete *Treponema denticola*. These organisms require the presence of late colonizers to attach to the biofilm. The pathogens produce several virulence mechanisms, allowing them to adhere to the epithelium lining the gums and invade the tissue, triggering an inflammatory response. PMN cells arrive and degranulate; the contents of their granules enhance inflammation. Cell-mediated and humoral-mediated immune responses also contribute to destruction of host tissue.

Initially, the inflammation, called *gingivitis*, is reversible and relatively mild. If the disease is allowed to progress because of poor oral hygiene and lack of medical intervention, the inflammation can extend to the periodontal support structures (ligaments, cementum, and alveolar bone), resulting in periodontitis. If the disease continues to progress, it can result in irreversible destruction of the ligaments and alveolar bone that hold the teeth in place, causing loosening of the teeth, pain, difficulty chewing, and eventually tooth loss. Gingivitis and mild periodontitis are considered relatively common. Periodontitis follows gingivitis, but it is not inevitable that periodontitis will develop following gingivitis.

Cystic fibrosis biofilm

CF is an important disease for which there is strong evidence that the chronic lung infection is the result of a biofilm. A variety of bacteria and fungi can be involved in the biofilm. Some bacteria that have been implicated include nontypeable *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *S. aureus*; the most predominant fungi are *Aspergillus fumigatus* and other *Aspergillus* spp. Infections with these bacteria are generally more amenable to treatment than the more common infections caused by *P. aeruginosa*, *B. cepacia*, *Stenotrophomonas maltophilia*, and *Achromobacter xyloso*. Up to 80% of patients with CF are chronically infected with *P. aeruginosa* by adolescence, and *P. aeruginosa* is the cause of death in most of this patient population. *P. aeruginosa* is an opportunistic human pathogen, meaning that this bacterium more commonly infects individuals with compromised host defenses. The bacterium is found in the environment in a variety of niches, such as in soil and water and on plants. In the hospital and long-term health care facility environments, the bacterium is often found in sinks, toilets, and floor mops, and it has been found in disinfectants. It causes a variety of infections because individuals in these facilities have compromised host defenses.

During infections, *P. aeruginosa* originally exists as planktonic bacteria or in enclaves of bacteria in which the bacteria later form a biofilm. In patients with CF, *P. aeruginosa* is thought to bind to the thick, viscous mucus commonly found in this patient population, forming aggregates. The bacteria frequently become mucoid from the production of an alginate slime layer. This mucoid material contributes to the extreme viscosity of the sputum produced by these patients. The change to the mucoid phenotype may allow the bacteria to increase their defenses against antimicrobial agents and host defenses. PMN cells are recruited to the biofilm and degranulate, causing tissue damage and provoking inflammation. The persistent inflammation, accompanied by bacterial toxins, contributes to the release of DNA, which has been shown to facilitate the formation of

biofilms. The inflammatory response produces most of the damage to the lungs, and over time, the result is respiratory failure.

There have been great strides in the treatment of *P. aeruginosa* infection in patients with CF. Daily inhalation of antimicrobial agents, such as tobramycin and colistin, is currently added to oral treatment regimens of ciprofloxacin, or intravenous (IV) antimicrobials consisting of a combination of an aminoglycoside and β -lactam are used. The use of inhaled antimicrobial agents allows the delivery of greater concentrations (100 to 1000 times) to the infected site than IV administration of the same drug. However, despite this intensive treatment of *P. aeruginosa* infections, the bacterial biofilm is never fully eradicated from the lungs. The intensive treatment does improve breathing and reduces the lung damage provoked by the infecting bacteria. Before the 1970s, about 50% of patients with CF would survive for 5 years; today, individuals can survive for decades.

Studies indicate that specific components of the host likely play a key role in the formation of biofilms in the CF lung. Therefore host factors, along with features of the infecting bacteria, must be considered when assessing the efficacy of new treatments. Although *P. aeruginosa* is the predominant bacterium associated with the biofilm found in adolescent patients with CF, evidence suggests that the biofilm consists of a variety of bacteria and fungi. However, the interaction of these various microorganisms in the biofilm is far from understood. The prevention or reversion of biofilm development likely would improve the quality of life of patients with CF.

Chronic upper respiratory tract infections

Studies have indicated that biofilm formation on the tonsillar tissue and adenoids can lead to chronic infections of the oral cavity and upper respiratory tract. Recurrent infections, most commonly by *S. aureus*, *Haemophilus* spp., and *Streptococcus* spp., result in hypertrophy of the tonsillar or adenoid tissue. There seems to be a link between the presence of biofilms and chronic inflammation. These biofilms might be a source of chronic pharyngitis and laryngitis. In addition, children with chronic otitis media with effusion (OME) were found to have biofilms covering part of the adenoids with OME pathogens. Similar results were found in children with chronic rhinosinusitis. When oral epithelial cells are covered with biofilms of *Streptococcus oralis* and *Streptococcus salivarius*, the cells are protected from colonization by *Streptococcus pyogenes*, a common cause of pharyngitis.

The changing paradigm of microbial infections

The understanding of chronic infections caused by organisms growing as biofilms has become more important. The role of IMDs cannot be underestimated in infections. IMDs are abiotic surfaces to which there is a natural aggregation of organisms that have a predilection for biofilm formation and the phenotypes associated with multispecies aggregates. [Table 31.4](#) lists the microorganisms associated with biofilms on IMDs. [Table 31.5](#) lists the usage and infection risk associated with IMDs in the United States, and the list is growing. In the area of dentistry alone, the use of implants and the growing treatment of patients without teeth will have a significant

Table 31.4 Microorganisms commonly associated with biofilms on indwelling medical devices

Microorganism	Indwelling medical device
<i>Candida albicans</i>	Artificial voice prosthesis
	Central venous catheter
	Intrauterine device
Coagulase-negative staphylococci	Artificial hip prosthesis
	Artificial voice prosthesis
	Central venous catheter
	Intrauterine device
	Prosthetic heart valve
	Urinary catheter
<i>Enterococcus</i> spp.	Artificial hip prosthesis
	Central venous catheter
	Intrauterine device
	Prosthetic heart valve
	Urinary catheter
<i>Klebsiella pneumoniae</i>	Central venous catheter
	Urinary catheter
<i>Pseudomonas aeruginosa</i>	Artificial hip prosthesis
	Central venous catheter
	Urinary catheter
<i>Staphylococcus aureus</i>	Artificial hip prosthesis
	Central venous catheter
	Intrauterine device
	Prosthetic heart valve

Table 31.5 Risk-related infections of indwelling medical devices in the United States

Device	Usage	Infection risk (%)
Bladder catheter	Tens of millions	10–30
Cardiac-assist devices	700	50–100
Cardiac pacemakers	400,000	1–5
Central venous catheters	5 million	5–8
Dental implants	1 million	5–10
Fracture fixators	2 million	5–10
Joint prostheses	600,000	1–3
Penile implants	15,000	2–10
Prosthetic heart valves	85,000	1–3
Vascular grafts	450,000	2–10

impact on the number of biofilm-associated dental infections beyond caries and periodontitis.

Ventilator-associated pneumonia, a condition that consumes more resources in the intensive care unit than any single infectious disease, is another example in which biofilms are an important disease-contributing factor. Pneumonia is the second most frequent hospital-acquired infection, and

86% of hospital-acquired pneumonias are ventilator-associated. Nearly 300,000 cases occur annually in the United States. The stress and shape of the endotracheal tube affect the cellular aggregation and fitness of the luminal biofilm, whether it is in the region closest to the ventilator, in the midsection (where the greatest turbulent stress is found), or in the section closest to the lung-endotracheal interface.

There are “good” and “bad” biofilms. In the human ecosystem, there is estimated to be more than 10^{14} bacteria. A hypothesis is that ecologic pressure is necessary for low numbers of pathogens to outcompete normal microbiota and achieve numeric dominance associated with diseases. Biofilms of stable normal biota represent a baseline organization. Biofilms of pathogenic organisms that overgrow normal biota and less virulent organisms because of selective pressures from antimicrobial agents are often associated with mismanagement. Microorganisms that are outcompeted often have low affinity for developing the biofilm phenotype. It is also important to remember that biofilm composition is reflective of the normal biota and location of IMDs placed close to the four reservoirs of normal biota: the gastrointestinal tract, genitourinary tract, oral cavity, and skin.

Laboratory consequences associated with biofilms

Historically, laboratory protocols focused on the idea that free-floating microorganisms were the most clinically significant. Clinical laboratories have maximized techniques that support the growth of planktonic organisms. However, broth cultures will not always facilitate the recovery of biofilm phenotypes, given that environmental conditions are required to convert a sessile phenotype to a planktonic phenotype. A broth culture incubated at 35°C with complex nutrients may not select for upregulation of an organism community. With greater understanding of biofilms and their significance in infections, better practices in the clinical microbiology laboratory must be developed.

With the emergence of biofilm-associated diseases, considerable diagnostic problems exist for the clinical laboratory. In general, these problems can be classified into five categories: (1) false-negative cultures, (2) viable but nonculturable organisms, (3) underestimated or low colony count, (4) inappropriate specimen, and (5) loss of or decreased antimicrobial susceptibility. Biofilms are resilient, adherent, and with EPS, resistant to culturing by swabs. False-negative culture results can occur because of improper sample collection. Studies have shown that cultures detect less than 10% of molecularly detectable methicillin-resistant staphylococci from vaginal specimens of biofilm communities. Some persister cells found in biofilms are viable but nonculturable, for reasons not fully understood. Organisms upregulated to the biofilm phenotype may have significantly altered biochemical profiles. These organisms will not grow under normal laboratory conditions. They may be visible on Gram-stained smears but might not be grown in culture media.

When bacteria are recovered from a biofilm, often aggregates representing 10^5 cells/mL or more can be recognized as a single colony on a bacteriologic plate. Hence the colony count may be significantly falsely reduced. Ignoring the

presence of a biofilm can result in the collection of inappropriate specimens. Until the true nature of biofilms was understood and the importance of stress realized, most organisms could be considered attached (as in arterial line sepsis) on the outside of the inserted line. It is now apparent that bacteria preferentially select a luminal environment, often devoid of immunologic components. The only technique that has been associated with the recovery of organisms from extraluminal sources is the rolling (Maki) technique. This is a semi-quantitative culture technique in which a 4-cm length of the catheter is rolled over the surface of an agar plate. Recovery of more than 15 colonies along with the same organism isolated from peripheral blood, with clinical signs and symptoms and no other recognized source of the organism, is suggestive of a catheter-related bloodstream infection. Currently, it is recognized that line sepsis is often intraluminal and that procedures must be developed to recover luminal organisms attached as biofilms. Central line-associated bloodstream infections are an important cause of morbidity and death; the Centers for Disease Control and Prevention (CDC) estimates that they contribute billions of dollars annually to U.S. health care costs.

Microbiology laboratories historically have performed antimicrobial susceptibility testing on organisms in the planktonic phenotype state in pure culture. This is associated with expressed gene markers and detection of drug resistance of an organism. In contrast, a community of cells loses its susceptibility as a phenotypic expression of that community. It is now accepted that the minimum inhibitory concentration against a free-floating planktonic isolate will increase by 10- to 1000-fold when measured in the biofilm community. Drug resistance is amplified even more when multiple species are present, particularly with the presence of prokaryotic and eukaryotic cells. Consequently, bacterial isolates that appear susceptible *in vitro* will not respond to therapy or can relapse several months later because of the existence of biofilms *in vivo*. Biofilm colonization of IMDs often requires removal of the device for a successful outcome.

Detection of biofilms and *in vitro* formation

The direct detection of biofilms on biopsied tissue, such as the middle ear mucosa in patients with chronic otitis media and on tissue or implants removed from diseased areas of the body, is now possible. Detection is based on the use of combined methods, such as polymerase chain reaction assay and pathogen-specific probes, along with special microscopic methods such as confocal laser scanning microscopy (CLSM). Although not performed routinely in clinical microbiology laboratories, these techniques provide valuable information about the role of biofilms in the disease process and what interventions are possible to eliminate or prevent biofilms.

Recently, our knowledge about the organisms that form biofilms has increased, allowing us to learn how to prevent them from initiating biofilm formation and to eliminate them. Methods used include observations by microscopic techniques (e.g., epifluorescence microscopy, CLSM, transmission electron microscopy, scanning electron microscopy)

or enumeration of sessile bacteria after detachment from the surface by scraping, vortexing, sonication, or the use of beads. These methods provide detailed information, but they are laborious and time-consuming and thus do not lend themselves to large-scale screening assays. Therefore more rapid and less laborious methods have been devised to evaluate the potential for bacteria to form biofilms in tubes or microtiter wells.

One rapid method is a colorimetric assay in which a suspension of bacteria is prepared in a culture medium that is then placed in the wells of a microtiter plate or tubes. After incubation for 24 to 48 hours, the medium is removed from the wells, and each well is rinsed several times to remove any bacteria not adhering to the vessel. Next, a stain, such as crystal violet or safranin, is added. After a specified time, the wells are rinsed several times, and then the wells are evaluated with a spectrophotometer for the presence of stain. The ability of the bacteria to form biofilms is determined by the degree of stain adhering to the bacteria in the vessel after rinsing. Techniques like this allow study of the effects an antimicrobial agent might have on the formation or inhibition of the growth of a biofilm. In a similar method, bacteria are incubated in the presence of silicone disks, and the ability of the bacteria to adhere to the disks is determined by a colorimetric method. Enhancement of this technique using preferential stains allows the determination of live and dead bacteria within the biofilm. The main problem with assays for the detection of biofilms or the potential of bacteria to form biofilms is the lack of standardization; therefore analysis of data from these studies must include a critical assessment of the methods used.

Potential interventions

Because of the inherently resistant nature of biofilms to antimicrobial therapy, biofilm inhibition strategies have been investigated. IMDs and biomaterials are ideal for microbial attachment. A common strategy to resist biofilm formation is to alter the composition of the device or its surface by adding a coating that is antiadhesive or repels attachment. Alternatively, applying low-molecular-weight biofilm inhibitors (e.g., phenol, imidazoles, furanone) has shown promise.

Traditional antimicrobial therapy based on planktonic susceptibility profiles will have a limited effect on resilient multispecies biofilms because of the physical and chemical properties of biofilms. Therapeutic modalities are focusing on multiple interventions, recognizing that the properties of biofilms resemble those of organic polymers, not planktonic microbes.

Because dispersed cells are generally more susceptible to antimicrobial treatment than biofilm-residing cells, biofilm dispersal has been investigated. Techniques to disperse biofilm are often based on interfering with metabolic pathways such as QS. A group of compounds referred to as **quorum-sensing inhibitors** (QSIs) or *quorum-quenching compounds* have been studied. These agents target bacterial signaling molecules, signal biogenesis, or signal detection, which disrupt the biofilm. An *in vitro* *P. aeruginosa* biofilm model found that a QSI used with an antimicrobial agent (ciprofloxacin, tobramycin, or colistin) had a statistically significant effect on biofilm reduction compared with

treatment with an antimicrobial agent alone. Also, the use of monoclonal antibody cocktails directed against the family of DNABII proteins has shown some success in disrupting biofilms. This disruption occurs because DNABII proteins serve as lynchpin proteins, positioned at the vertices of the cross-strands of extracellular DNA within the biofilm. Disruption of these proteins results in destabilization of the biofilm, causing it to disaggregate. Disruption of the biofilm and its aggregates could have clinical consequences that are detrimental to the patient. Disaggregation of upregulated phenotypes could be associated with metastasis. Therefore dispersal methods should be used in conjunction with antimicrobial agents.

Biofilm eradication agents are stand-alone antimicrobial agents that target and eliminate biofilms. In addressing biofilm eradication, various strategies have been tested: (1) antimicrobial agents, (2) mechanical disruption or removal (sonication), and (3) immune modulation. Other schemes to address biofilm-associated diseases have had limited success. Antimicrobial peptides are some of the most studied types of biofilm eradication agents. They have a molecular weight of 1 kDa to 5 kDa and are typically cationic (positive charge). Their mode of action is not well understood, but they disrupt cytoplasmic membranes and inhibit protein folding or enzyme activity. LL-37 was one of the first compounds to demonstrate the ability to reduce the thickness of biofilms. Oritavancin, a semi-synthetic lipoglycoprotein, has also shown promise.

Quaternary ammonium compounds are a large class of antimicrobial agents also investigated as biofilm eradicating agents. They disrupt bacterial plasma membranes, leading to metabolite leakage and eventually cell lysis. Several other compounds, including antimicrobial lipids (fatty acids), anti-cancer drugs (mitomycin C and cisplatin), phenazines, and quinolones, have been investigated.

The effects of various antimicrobials, used alone or in combination, on the elimination or reduction in the number of organisms in a biofilm or the prevention of biofilms have been studied. For example, a comparative analysis of the activities of daptomycin, linezolid, minocycline, tigecycline, and vancomycin used alone or in combination with rifampin against catheter-related methicillin-resistant *Staphylococcus aureus* (MRSA) bacteremic isolates embedded in biofilm was performed. The study found that when used alone, minocycline, daptomycin, and tigecycline were more efficacious in inhibiting the MRSA in the biofilm than linezolid, vancomycin, and the negative control. Daptomycin by itself was found to be the fastest in eradicating the MRSA biofilm. Rifampin alone was not effective in eliminating the MRSA biofilm; however, when it was used in combination with other antimicrobials, it enhanced the performance compared with when antimicrobials were used alone. This study illustrates the effects antimicrobials might have on a monospecies biofilm. No generalizations can be made, however, about the effect of any one antimicrobial on biofilms formed by multispecies biofilm.

Another approach to eliminating biofilms uses bacteriophages genetically engineered to express a biofilm-degrading enzyme called *dispersion B* (DspB) to attack the bacterial cells in the biofilm and biofilm matrix (i.e., EPS) simultaneously. Initial studies showed that the engineered phage achieved 99.9% removal of a biofilm produced by *E. coli* on plastic

pegs. This approach eliminates the need to express, purify, and deliver large doses of enzyme to specific sites of infection, all of which can be difficult. This approach is an example of synthetic biology, which over the years has enabled the development of many engineered biological devices. Synthetic biology is distinguished from traditional genetic engineering by using modularity, abstraction, and standardization to allow generalized principles and designs to be applied to different scenarios. This is an example of applied microbiology.

Biofilm models for studying antimicrobials

Establishing biofilms in 96-well plates has allowed a quantitative measurement of biofilms termed *minimal biofilm elimination concentration*. This assay quickly screens biofilms for drug resistance. In theory, disk diffusion antimicrobial testing should be related to antimicrobial-resistance testing, and biofilm testing or colonization resistance can be associated with antimicrobial susceptibility testing.

Numerous methods have been devised for studying the effects of antimicrobials on biofilms, including animal and human in situ models. The ethical implications for conducting animal and human studies must be considered carefully. Many complexities must be evaluated when devising methods or designing an apparatus for antimicrobial testing of biofilms. For example, it has been shown that the way bacteria associate with the surface influences the susceptibility of the biofilm to antimicrobials. Some of the biofilm models that have been used include:

- CDC Biofilm Reactor. Biofilms are grown on coupons (stainless steel or porcelain disks) exposed to a continuous culture, with the coupons then exposed to antimicrobials.
- Modified Robbins cell. This is like the CDC Biofilm Reactor, except that the coupons can be removed from the device and exposed to individual antimicrobials.
- Flow cell. Biofilms are grown in a continuous or batch culture with direct visualization of the biofilm possible; the biofilms can be exposed to antimicrobials.
- Membrane filters. Biofilms are grown on the surface of a membrane filter placed on an agar surface, which can then be exposed to antimicrobials.
- Microtiter plate. Biofilms are grown on plastic pegs; the pegs with the biofilm are placed into different concentrations of antimicrobials.

Do all members of a microbial community have to be grown in pure culture and tested individually, or is it sufficient to grow and test a mixed culture? Because modern molecular techniques have demonstrated that microbial communities affect disease outcome, the need to incorporate microbial communities into disease diagnosis and treatment has become ever so important. There is a need for the scientific community to consider infectious disease causation in a broader systems biology context. Host genetic variability, health status, and past exposure to antimicrobials and perhaps to other drugs and microbes individually and in communities now must be considered if the appropriate clinical response to treatment is to be achieved.

POINTS TO REMEMBER

- All microorganisms, including prokaryotes and eukaryotes, can exist in two phenotypes: planktonic and sessile.
- Biofilms likely evolved as a means of increasing microbial survival.
- Biofilms have unique properties, which are described and quantified by physical and chemical measurements, including rheology and viscoelasticity.
- Pathogenicity associated with biofilms is not a total of the individual phenotypes but rather a combination of the entire community of cells. Expression of disease is particularly associated with immunologic and inflammatory cascade and resultant tissue injury, with limited microbial injury.
- The staging of biofilms is critical in disease progression; the ratio of biofilm to planktonic phenotypes is a predictor of virulence or pathogenicity.
- Biofilms are innately more tolerant to antimicrobial agents than their individual planktonic counterparts.
- The presence of IMDs increases the risk for biofilm formation and subsequent infection.
- Many infections in animals follow monospecies or multispecies biofilm formation.
- Interventions against biofilms include treating IMDs to prevent biofilm formation and using biofilm eradication agents and combination antimicrobial agents.
- Biofilms are not recovered or recognized by standard laboratory protocols. Routine susceptibility testing does not accurately predict the success of antimicrobial therapy for biofilm phenotypes.

LEARNING ASSESSMENT QUESTIONS

- Which of the following surfaces is most susceptible to biofilm formation?
 - Liquid
 - Rough
 - Smooth
 - Metal
- At which location in a biofilm are most persister cells likely to be found?
 - Surface
 - Middle layer
 - Aqueous layer
 - Bottom layer
- What is the sticky matrix that makes up the majority of the nonaqueous portion of a biofilm?
 - Sialic acid
 - Cathelicidin
 - Exopolysaccharide
 - N-acyl homoserine lactone
- What is the first step in biofilm formation on the surface of teeth?
 - Glycolyx synthesis
 - Pellicle formed from host proteins
 - Release of quorum-sensing inhibitors
 - Bacterial teichoic acid binding to tooth enamel
- How does the planktonic phenotype differ from the sessile phenotype?
 - The planktonic phenotype often expresses pili, and the sessile phenotype does not.
 - The sessile phenotype is adapted for free-swimming, and the planktonic phenotype is attached.
 - The planktonic phenotype often produces exopolysaccharide, and the sessile phenotype does not.
 - The planktonic phenotype disaggregates forming a new biofilm, and the sessile phenotype does not.
- What is the primary trigger for inflammation in gingivitis?
 - Acid production by bacteria on tooth surface
 - Hypersensitivity reaction to bacterial allergens in a biofilm
 - Bacterial toxins released by bacteria in a biofilm in the sulci
 - Bacterial toxins released by bacteria in a biofilm on the tooth surface
- Recurrent otitis media with effusion has been linked to biofilm formation on which of the following?
 - Adenoids
 - Epiglottis
 - Nasopharynx
 - Trachea
- What is the primary disadvantage of using the rolling (Maki) technique for culturing arterial catheter tips?
 - Low sensitivity
 - Prone to contamination
 - Requires prolonged incubation
 - Only recovers extraluminal bacteria
- Which bacterium is a significant cause of morbidity and mortality in patients with cystic fibrosis as a result of biofilm formation?
 - Bordetella parapertussis*
 - Escherichia coli*
 - Pseudomonas aeruginosa*
 - Staphylococcus aureus*
- What is the best strategy in controlling biofilm-associated infections related to indwelling medical devices?
 - Using treated synthetic materials that prevent biofilm formation
 - Administering a single high dose of a broad-spectrum antimicrobial agent
 - Administering multiple low doses of a broad-spectrum antimicrobial agent
 - Using organic solvents to dissolve the biofilm matrix
- Describe the five cycles of biofilm formation.
- How do biofilms aid microbial attachment to solid surfaces?
- How is a typical mature multispecies biofilm structured?
- How do biofilms increase microbial tolerance to antimicrobial therapy?
- What are the three virulence mechanisms of biofilms?
- Why do indwelling medical devices increase the risk of bacterial infection?
- What are three areas of concern for clinical microbiologists when dealing with biofilm-associated microorganisms?
- What methods can be used to study biofilm formation in vitro?
- Why does the disruption of a biofilm have serious consequences for a patient?
- How do monoclonal antibodies disrupt biofilms?

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Explain the mechanical defenses of each anatomic site and how alterations to these defenses may result in infectious diseases.
2. Explain the importance of normal biota in the respiratory tract and how alterations in the normal biota may result in infectious diseases.
3. Discuss the basic pathogenic mechanisms of infectious disease agents of the respiratory tract and the virulence factors that contribute to disease.
4. Describe the most common organisms causing upper and lower respiratory tract infections.
5. Describe the pathogenesis, risk factors, and complications associated with respiratory tract infections.
6. Summarize the risk factors in immunocompromised hosts that predispose them to infections and include examples of respiratory tract diseases in different types of immunocompromised hosts.
7. Recommend types of specimens that should be collected for the diagnosis of respiratory tract infections.
8. Describe the principles and methods of proper specimen collection and transport of respiratory secretions.
9. Justify the direct visual examination of respiratory samples.
10. Describe newer and emerging respiratory infections.
11. Determine the agents of bioterrorism as related to respiratory tract infections.
12. Appraise the important aspects of the diagnosis of infections of the respiratory tract through case studies.
13. Justify the increasing role of non-culture-based rapid diagnostic testing including molecular methods in diagnosing respiratory tract infections.

KEY TERMS

Acute otitis media (AOM)

Aspiration pneumonia

Bronchiolitis

Bronchitis

Community-acquired pneumonia (CAP)

Empiric antimicrobial therapy

Empyema

Epiglottitis

Healthcare-associated infection

Parapneumonic effusion (PPE)

Pertussis

Pharyngitis

Pneumonia

Sinusitis

Ventilator-associated pneumonia (VAP)

Case in point

A 52-year-old female patient came to the emergency department complaining of right-sided chest pain with each breath, a cough that produced rust-colored sputum, and fever. She reported that her symptoms began abruptly the day before, with the onset of shaking chills. Examination revealed that the patient had a fever of 102° F (38.8° C) and coarse breath sounds in the right anterior chest. The chest x-ray (see Fig. 32.5 later in the chapter) showed a right lung upper lobe infiltrate; the laboratory analysis included an elevated white blood cell count.

Issues to consider

After reading the patient's case history, consider:

1. How mechanical and functional changes in the upper and lower compartments of the respiratory tract can lead to infection
2. The importance of the respiratory tract normal biota in preventing colonization by potential pathogens and how alterations in the normal biota and colonization of normally sterile areas may lead to infection
3. How microbial virulence factors relate to the establishment and progression of infection
4. Clinical manifestations of upper and lower respiratory tract infections and the pathogenesis, risk factors, and complications of specific disease states
5. Infections in previously healthy hosts and how presentations of these infections differ in immunocompromised patients

This chapter describes respiratory tract infections from the perspective of the clinical microbiologist working with the primary care provider who must make the differential diagnosis of these infections. General concepts of infectious diseases of the respiratory tract are discussed, including the role of normal microbial biota in preventing infection and the importance of the host's immune status in determining the pathogens likely to cause disease. It outlines the anatomy of

the respiratory tract with consideration given to natural barriers to infection. The chapter proceeds with a discussion of specific respiratory tract infections organized according to anatomic site. The causes, pathogenesis, clinical manifestations, and complications of specific diagnoses are discussed, and emphasis is placed on appropriate methods of laboratory diagnosis. Respiratory tract infections in immunocompromised hosts are described. The chapter ends with respiratory tract infections caused by agents considered to be the most likely to be used in acts of bioterrorism.

General concepts of infectious diseases of the respiratory tract

Anatomy of the respiratory tract

The function of the respiratory tract is not only to perform respiration (i.e., the exchange of oxygen and carbon dioxide) but also to deliver air from outside the body to the alveoli, where gas exchange occurs. Consideration of the anatomy of the respiratory tract (Fig. 32.1) must include the entire course that air must travel—from the mouth and nose through the sinuses, into the pharynx, past the epiglottis, through the larynx, into the trachea and bronchi, and eventually into the alveoli. In addition to a role in air transport, each of these areas also plays an important role in defending the respiratory tract against infection.

Barriers to infection

The respiratory tract has many natural barriers to infection that inhaled organisms must overcome before they can cause disease. Among the elements of the respiratory tract and its functions that help prevent infection are nasal hair, mucociliary cells that line mucosal surfaces, coughing, normal

Fig. 32.1 Anatomy of the respiratory tract.

biota, secretory immunoglobulin, defensins, and phagocytic inflammatory cells.

In the nasopharynx and oropharynx, turbulent air flow causes large particles to have an impact on mucosal surfaces. Nasal hairs filter air as it passes through the nasal passages. Humidification of the air causes hygroscopic particles to increase in size, making it more likely for them to be cleared by mechanical mechanisms of the upper respiratory tract. The normal biota of the nasopharynx and oropharynx help protect the host by preventing colonization by pathogenic organisms. The mucociliary blanket of the sinuses, middle ear, and tracheobronchial tree clears particulate matter and contains immunoglobulin and other antimicrobial substances. In addition, coughing aids in the clearance and expulsion of particulate matter. If particles reach the alveoli, resident macrophages ingest microorganisms; polymorphonuclear leukocytes and monocytes are recruited once the lung becomes inflamed. Alterations in these barriers can lead to infection. For example, cigarette smoking impairs the ability of the ciliated respiratory epithelium to clear particulate matter and interferes with phagocytic cell activity. Structural abnormalities of the bronchial tree such as bronchiectasis or extrinsic compression of the bronchus by a malignancy can alter the clearance of mucus, which may contain infectious agents.

The role of normal biota

The normal microbial biota (formerly referred to as *flora*) protects the host from infection with pathogenic microorganisms. The normal biota can prevent proliferation and invasion of pathogenic organisms through competition for nutrients and the same receptor sites on host cells. In addition, some of these organisms produce bacteriocins, bacterial products that are toxic to potential pathogens. The presence of these organisms keeps the immune system primed for a rapid response to invading organisms and stimulates cross-protective immune factors termed *natural antibodies*. Under normal conditions, a balance of organisms is maintained that limits the quantity or dominance of any one type of organism.

Although a standard list of organisms can be routinely cultured from the upper respiratory tract (Box 32.1), it is interesting that the consensus concerning what is considered normal biota can change over time as new associations between organisms and disease states are recognized. For example, previously *Moraxella catarrhalis* was considered part of the normal upper respiratory tract biota that was only rarely associated with serious infections. However, since the early 1970s, it has become clear that this organism can cause respiratory tract infections in children and adults with chronic lung disease. This indicates the importance of periodic reevaluation of the pathogenicity of all organisms.

Familiarity with the normal biota of respiratory tract compartments is important in determining the clinical relevance of diagnostic testing results. For example, isolation of α -hemolytic colonies from a pharyngeal culture from a patient with pharyngitis arouses little clinical interest because α -hemolytic streptococci are normal biota in the oropharynx. In contrast, isolation of α -hemolytic colonies from a properly collected sputum specimen or bronchial aspirate in the clinical setting of lobar pneumonia should prompt full identification of the organism and perhaps initiation of empiric therapy for possible pneumococcal infection.

BOX 32.1 Normal nasopharyngeal and oropharyngeal organisms

Bacteria

Usually present

Streptococcus mitis group (including *Streptococcus pneumoniae*),
Streptococcus salivarius group, and other viridans streptococci
 Non-group A β -hemolytic streptococci
 Nonhemolytic streptococci
Veillonella spp.
Bacteroides spp.
Fusobacterium spp.
Prevotella spp.
Porphyromonas spp.
 Coagulase-negative staphylococci
Neisseria spp.
 Diphtheroids
Micrococcus spp.
Eikenella spp.
Capnocytophaga spp.

Occasionally present

Haemophilus influenzae
Haemophilus parainfluenzae
Peptostreptococcus
 Actinomycetes
Staphylococcus aureus
 Mycoplasma

Fungus

Candida spp.

Distinguishing among normal biota, colonizing, and pathogenic microorganisms

The upper respiratory tract biota in an asymptomatic patient may change, depending on the clinical setting. Patients who have previously received broad-spectrum antimicrobials, have been hospitalized recently, or have a chronic illness may have different pharyngeal biota. Gram-negative bacilli are commonly isolated from the pharynx in these patients in the absence of clinical signs of infection. Therefore it is important to distinguish between a culture positive for a potential pathogen colonizing the respiratory tract and the clinical disease state caused by that organism. Box 32.2 lists organisms that are considered primary pathogens. Also shown are a number of organisms that may or may not be pathogens, depending on the clinical setting (i.e., possible pathogens). In this case, as in many others, proper communication between the clinical microbiologist and primary care provider is essential.

Proper respiratory specimen collection increases the sensitivity and specificity of culture results. A high-quality sputum sample that minimizes contamination by oral biota and is collected before initiation of antimicrobial therapy improves the clinical value of the culture results. Interpretation of the result must be based on several factors. Characteristics of the specimen, such as the presence of white blood cells (WBCs) and number of organisms in the specimen, can help distinguish between colonization and infection. Most importantly, a compatible clinical syndrome should be present to determine whether the presence of a potential pathogen is clinically relevant. For example, isolation of a few colonies of *Staphylococcus aureus* from a sputum specimen with many

BOX 32.2 Selected nonviral pathogens in the respiratory tract**Primary pathogens**

Streptococcus pneumoniae
 Group A β -hemolytic streptococci
Staphylococcus aureus
Haemophilus influenzae
Neisseria gonorrhoeae
Bordetella pertussis
Mycobacterium avium complex
Mycobacterium chelonae-abscessus complex
Mycobacterium kansasii
Mycobacterium tuberculosis
Legionella pneumophila
 Toxin-producing *Corynebacterium diphtheriae*
Mycoplasma pneumoniae
Chlamydia trachomatis
Chlamydia pneumoniae
Pneumocystis jiroveci

Possible pathogens

Acinetobacter spp.
Pseudomonas aeruginosa
 Enterobacterales
 Fungi
Nocardia spp.
 β -Hemolytic streptococci, non-group A
Moraxella catarrhalis
 Anaerobes (e.g., *Fusobacterium necrophorum*)
 Actinomycetes

epithelial cells does not suggest *S. aureus* pneumonia but is more likely to be contamination with an organism that is part of the normal biota. In contrast, heavy growth of the same organism from a respiratory specimen with many WBCs from an older patient with postinfluenza pneumonia is highly suggestive of *S. aureus* pneumonia, especially if the sputum culture is accompanied by a positive culture from a normally sterile site, such as blood or pleural fluid.

Other organisms are potentially pathogenic and cause disease only when some interruption occurs in the pulmonary defense mechanisms. *Streptococcus pneumoniae* has been isolated from 5% to 70% of the normal adult population, yet only a very small proportion of these carriers will develop pneumococcal pneumonia. Pneumonia can also result from aspiration of upper respiratory tract secretions in patients with impaired pulmonary defenses, such as those with alcoholism or congestive heart failure. Other organisms are always considered pathogenic when isolated, even in small numbers. Isolation of *Mycobacterium tuberculosis* in any amount is significant because of the virulence of the organism and the risk for transmission from the infected patient to others.

Host risk factors**Immune status of the host**

When considering the likelihood that a microorganism will cause infection in a given host, the laboratory scientist must consider the virulence of the agent and the host defenses to counteract establishment and progression of infection. For these

purposes, a normal host is considered to be one with mature immunologic defenses who may or may not have specific immunity against the infectious agent in question. Examples of agents that cause respiratory tract infections in normal hosts include the common respiratory viruses of childhood. In normal children, these viral infections occur at a high incidence but are usually relatively benign. The clinical outcomes of these and other respiratory tract infections in normal hosts depend on the injurious effects of the microorganism and its products at the site of infection and the host's response to infection.

Previous exposure of a host to pathogens, such as the respiratory tract viruses, is one example in which the host usually develops immunity to reinfection with the same agent. Immune responses may prevent or alter the course of subsequent infection. For example, adults previously infected with a given viral serotype as children usually do not manifest the same severity of infection when reexposed to the same pathogen. Evidence of infection may not be present, or clinical signs and symptoms of infection may be greatly reduced. In an immunocompromised host, however, microorganisms that are usually not pathogens in a normal host may cause serious infection. This type of infection is referred to as an **opportunistic infection** (OI) to indicate the combination of a reduced host response and a pathogen of low virulence that results in the establishment of infection. Because the host response is diminished, infections with highly virulent pathogens are usually more severe and more rapidly progressive than in the immunocompetent host.

Age as a risk factor

Immunocompromise because of age is a form of functional immunodeficiency. Infants and older adults are more susceptible to certain infections and are more likely to develop complications of these infections. For example, respiratory tract infections with *Haemophilus influenzae* are more commonly complicated by meningitis in infants than in older children or adults. Similarly, in older adults, complications of common respiratory tract infections occur more frequently than in the younger adult population. One hallmark of seasonal outbreaks of influenza virus infection of the respiratory tract is the increased incidence of death from complicating bacterial pneumonias in older adults.

Thus it is apparent that one cannot determine the significance of a respiratory tract microbial isolate without considering the source of the specimen, age and immunologic status of the host, and clinical setting of the patient. The isolation of a potential pathogen may represent simple colonization of the upper respiratory tract or life-threatening disease. In contrast, isolation of a nonpathogenic organism that may be part of the normal biota of the upper respiratory tract may be an indication of disease if found in an unusual location or in a host with decreased defenses against infection. Availability of complete clinical data facilitates proper evaluation of the respiratory tract specimen by the clinical microbiologist.

Reduced clearance of secretions

Reduced clearance of secretions or obstruction of an area in the upper or the lower respiratory tract predisposes one to infection and can, on occasion, seriously compromise respiratory tract function. Mechanical clearance is important in limiting the numbers of potential pathogens and in the associated

inflammatory response. Decreased clearance of respiratory secretions may result from the following:

- Immature anatomic development (e.g., eustachian tube anatomy in young children)
- Transient reduction in function of the mucociliary mechanism (e.g., after viral infection or as a result of cigarette smoking)
- Obstruction by a foreign body (e.g., aspirated food or foreign object)
- Previous disease that alters the normal respiratory tract anatomy (e.g., bronchiectasis, obstructing lymph node or tumor)
- Increased viscosity of mucus (e.g., cystic fibrosis)

Infection-induced airway obstruction

Another way in which respiratory tract obstruction can be a factor in infectious disease involves compromise of respiration. In these cases, the obstruction may be a consequence of infection, rather than the factor that precipitates infection. The anatomy of the area, rather than the type of pathogen, dictates the urgency with which treatment is initiated. An example of this type of respiratory tract infection is acute epiglottitis (see later) caused by infection of a nonimmune patient with *H. influenzae*. This inflammatory response to bacterial infection can cause life-threatening upper airway obstruction and is considered a medical emergency. In contrast, other infections caused by the same pathogen, such as sinusitis, can be treated more deliberately.

Seasonal and community trends in infections

Awareness of the patterns of respiratory tract infections at different times of the year in the community in which the patient resides is important for the efficient use of diagnostic microbiology resources. Some respiratory tract infections have a peak seasonal incidence and may produce epidemics in the community. Viral respiratory tract infections, for example, are more common in the winter months. Therefore if influenza virus infection is epidemic in the community and a patient presents with symptoms and signs compatible with this viral illness, the likelihood is high that influenza is the cause of the infection. In such cases, performing extensive bacterial cultures to define the cause of the respiratory tract infection may be a wasteful use of resources unless a secondary infection is suspected.

In contrast, diseases associated with *Mycoplasma pneumoniae* typically occur throughout the year, without marked seasonal variability. The incidence of viral infections and secondary bacterial pneumonias is reduced during the summer months; therefore *M. pneumoniae* may cause up to 50% of all pneumonias in the summer months. Communication among clinical microbiologists, primary care providers, and state health department personnel sharing information on community trends in the pathogens causing respiratory tract infections helps focus diagnostic and therapeutic efforts.

Empiric antimicrobial therapy

To properly position the diagnostic microbiology laboratory in the scheme of the patient health care, it is important to understand the role of **empiric antimicrobial therapy** in the

care of patients with respiratory tract infections. Although basing antimicrobial therapy on the results of diagnostic microbiological studies is desirable, certain circumstances dictate that therapy be initiated before obtaining these results or even without submitting specimens for testing. For example, antimicrobial therapy should be initiated before obtaining microbial identification and susceptibility testing results in patients who are seriously ill with pneumonia. In some types of respiratory tract infections, it is standard to initiate antimicrobial therapy without obtaining specimens for culture, such as in children with middle ear infections (otitis media) when the pathogen can reasonably be predicted in most cases without resorting to an invasive procedure. This same rationale applies to other respiratory tract sites that are difficult to culture directly, such as the sinuses.

When empiric antimicrobial therapy is necessary, it is important to have a working knowledge of the organisms most likely to cause the type of infection observed and of the antimicrobial agents most likely to be effective. The microbiology laboratory can provide preliminary data on the possible identity of the pathogen based on Gram staining results and preliminary biochemical studies (e.g., lactose fermentation by gram-negative bacilli). Multiplex molecular diagnostic panels are also being increasingly utilized to detect common pathogens in clinical specimens including from respiratory and blood specimens within hours before the availability of culture result.

If the infection is a **healthcare-associated infection**, it is important to know whether the antimicrobial susceptibility patterns of the infectious agent in question differ from those found in the community. Periodic reviews of bacterial antimicrobial susceptibility patterns are published by clinical microbiology services to facilitate this type of decision-making process; these are termed *cumulative antibiograms*. Empiric use of antimicrobial agents and adjustment of therapy based on the results of subsequent microbiological data represent other important interactions between the primary care provider and clinical microbiologist.

Virulence factors of pathogenic organisms

The disease-producing capability of an organism is the clinical manifestation of its virulence. Microorganisms cause infection by entering the host, interacting with specific target tissues, evading the host's defenses, proliferating, damaging the host, and disseminating or elaborating products that cause systemic disease. Virulence factors involved in disease-producing mechanisms, such as adherence, toxin elaboration, and host evasion, enable the microorganism to complete this process. See [Chapter 2](#) for a discussion of host-parasite interactions.

Attachment of the bacterial pathogen to the mucus membranes is a primary step in the initiation of a respiratory tract infection. Attachment is made possible by adhesins or other microbial surface molecules or pili that bind the organism to a host surface. Specific bacterial adhesins interact with specific cellular receptors. For example, *Streptococcus pyogenes*, possess fimbriae, which are fine, irregular structures composed of M protein and lipoteichoic acid that bind to epithelial cells.

Microorganisms may elaborate toxins that produce different pathogenic effects, depending on the activity of the toxin and the target cell with which it interacts in the host. For example, *Corynebacterium diphtheriae*, the cause of diphtheria, produces a toxin that interferes with protein synthesis. Locally, the toxin induces necrosis, resulting in the formation of a pseudomembrane in the pharynx composed of necrotic respiratory epithelial cells, leukocytes, and organisms. This pseudomembrane can cause airway obstruction. Systemically, the toxin preferentially adheres to myocardial, nerve, and kidney tissue, causing myocarditis, neuritis, and renal tubular necrosis. The mechanism of action of *Pseudomonas aeruginosa* exotoxin A resembles that of diphtheria toxin, but it has a different pathogenic effect because of different target tissue and involvement of other virulence factors.

Evasion of host defenses enables microorganisms to proliferate and cause damage to the host. Certain respiratory pathogens, such as *S. pneumoniae*, *H. influenzae*, and mucoid *P. aeruginosa* strains, evade host defenses by expressing polysaccharide capsules that prevent phagocytosis by WBCs. Chlamydiae are obligate intracellular parasites taken up by host cells, where they are protected from the host immune system. *M. tuberculosis*, another intracellular pathogen, survives by inhibiting phagosome-lysosome fusion. Other respiratory pathogens are able to cleave host secretory antibodies by producing immunoglobulin A (IgA)-specific proteases.

Case check 32.1

Symptoms of acute pneumonia, as seen in the Case in Point, can arise suddenly with the patient appearing quite ill. These patients typically have a productive cough that can be blood-tinged as a result of severe inflammation occurring in the lungs. *Streptococcus pneumoniae*, an encapsulated bacterium, is the number one cause of bacterial pneumonia. The mortality rate can be high, especially in older adult patients.

Upper respiratory tract infections

Pharyngitis

Case study

An 8-year-old female patient was brought to the emergency department by her mother because the child was complaining of a sore throat and had a low-grade fever. The mother stated that her daughter had had a runny nose and cough for the past few days. On examination, the patient had a fever of 99° F (37.2° C). Her oropharynx was red, and her tonsils were slightly swollen, but no exudate was present. A neck examination revealed no tender lymph nodes.

Epidemiology

Sore throat, or **pharyngitis**, is one of the most common reasons patients visit their primary health care providers, resulting in 11 million office visits annually in the United States. Most pharyngeal infections occur in the winter and early spring. β -hemolytic

group A streptococci (GAS) and other respiratory pathogens are usually acquired by inhalation of aerosols or by contamination of the hands with droplets and then inoculation into the upper respiratory tract. In some cases, this acquisition leads to symptomatic disease, whereas in others, patients simply become asymptomatic carriers. During peak season, up to 15% of school-age children may be asymptotically colonized with GAS, which can complicate diagnosis.

Causes

Table 32.1 summarizes the clinical syndromes encountered in the upper respiratory tract and the common associated causative agents. Most pharyngitis cases in all age groups are caused by viruses, including rhinovirus, coxsackie virus, coronavirus (including severe acute respiratory syndrome coronavirus-2 [SARS-CoV-2]), adenovirus, parainfluenza virus, Epstein-Barr virus (EBV), and influenza virus. A less common but important viral cause to consider is HIV, which can manifest as a sore throat during the acute phase of the infection. The most common bacterial cause of pharyngitis is *Streptococcus pyogenes*, a β -hemolytic GAS. Identified in 15% to 30% of children 5 to 15 years of age who present with pharyngitis, GAS are isolated much less frequently (<15%) in adults and very young children with a similar clinical presentation. Other β -hemolytic streptococci, including groups C and G, are often isolated in culture. Group C streptococci have been associated with pharyngitis in college students and young adults; the role of group G streptococci is less clear.

Less common causes of pharyngitis include bacterial pathogens such as *Neisseria gonorrhoeae*, *Arcanobacterium haemolyticum*, *Corynebacterium diphtheriae*, and *Fusobacterium necrophorum*. *C. diphtheriae* causes diphtheria, a highly contagious and potentially fatal form of bacterial pharyngitis that is transmitted through close contact or inhalation of bioaerosols from infected patients. However, it is now uncommon in the United States and most of the developed world because of the widespread use of diphtheria vaccination. This infection should be suspected in patient populations in whom vaccination rates are low, such as in developing countries and potentially in underserved U.S. populations.

Pathogenesis

The reasons for the symptoms in patients with viral or streptococcal pharyngitis are incompletely understood. Some viruses (e.g., adenoviruses) that infect the pharyngeal mucosa cause cellular destruction (cytopathology); all such infectious agents elicit inflammatory cell responses. The combination of these events is responsible for the pharyngeal pain and swelling experienced by patients with pharyngitis. However, in other cases, the viral pathogens (e.g., rhinoviruses) cause symptoms of pharyngitis with little mucosal cell destruction. In some cases, these noncytopathic viruses have been shown to elicit the production of inflammatory mediators that can reproduce the symptoms of pharyngitis.

The pathogenesis of streptococcal pharyngitis may be caused mainly by the inflammatory effects of a variety of extracellular products elaborated by the bacteria. These products exhibit various activities, including toxicity to a variety of cells, pyrogenicity, and enhancement of the spread of streptococci through infected tissues.

Table 32.1 Upper respiratory tract infections

Clinical syndrome	Causative agents	Specimen collection	Other
Pharyngitis	Children: Viruses <i>Streptococcus pyogenes</i> (15%–30%) Adults: Viruses <i>Streptococcus pyogenes</i> (5%–15%)	For <i>S. pyogenes</i> culture, swab tonsils and posterior pharynx, and place in transport media; rapid strep testing available and often performed at point of care	For epidemiologic purposes, a test for SARS-CoV-2 is now commonly performed If clinically indicated: • Culture for <i>Corynebacterium diphtheriae</i> • Nucleic acid amplification test or culture for <i>Neisseria gonorrhoeae</i> • HIV RNA PCR • Monospot test for EBV
Sinusitis	<u>Most common</u> Rhinovirus Parainfluenza virus Influenza virus <u>Less common</u> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	Direct sinus sampling as needed	Direct sampling indicated for patients who fail empiric therapy, are severely ill, are immunocompromised, or in whom intracranial extension is suspected
Otitis media	<u>Most common</u> <i>S. pneumoniae</i> <i>H. influenzae</i> <u>Less common</u> <i>S. pyogenes</i> <i>Moraxella catarrhalis</i> <i>Staphylococcus aureus</i>	Empiric therapy is used in the majority of cases Direct culture by tympanocentesis as needed	Direct culture indicated for patients who are severely ill, have failed empiric antimicrobial therapy, or have suspicion for an unusual or drug-resistant pathogen
Epiglottitis	<u>Most common</u> Streptococci Staphylococci <i>H. influenzae</i> <u>Less common</u> <i>Haemophilus parainfluenzae</i>	Blood cultures	Direct swab should be performed only if airway is secure
Pertussis	<u>Most common</u> <i>Bordetella pertussis</i> <i>Bordetella parapertussis</i> <u>Less common</u> <i>Bordetella bronchiseptica</i> <i>Bordetella holmesii</i>	Nasopharyngeal swab: • PCR testing • Plate directly onto Bordet-Gengou or Regan-Lowe medium for culture	If very late in the course of the disease, serologic testing may be more beneficial if other testing is negative

EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; PCR, polymerase chain reaction.

Clinical manifestations

Clinically, differentiation between viral and streptococcal pharyngitis is difficult. Symptoms of a common cold, including rhinorrhea (watery mucus discharge from the nose), conjunctivitis, and cough, are more often associated with a viral cause; influenza virus infection is often accompanied by fever, diffuse myalgias (muscle aches), and profound fatigue.

Case check 32.2

The modified Centor criteria, which include fever, anterior cervical lymphadenopathy, tonsillar or pharyngeal exudates, and the absence of cough, are often used to risk-stratify patients for the likelihood of GAS throat infection; the more criteria present, the greater the likelihood of GAS infection. The age of the patient is also considered. As in the introductory case of the 8-year-old patient with a sore throat and low-grade fever, without swollen lymph nodes and other symptoms (rhinorrhea) more consistent with a viral infection, the use of criteria such as these is recommended to determine which patients require testing and/or empiric therapy.

Infectious mononucleosis caused by EBV or cytomegalovirus (CMV) may be suspected based on posterior cervical or generalized lymphadenopathy (swelling of the lymph nodes) and splenomegaly. Acute HIV seroconversion is also often accompanied by generalized lymphadenopathy as well as fever and a diffuse rash.

Streptococcal pharyngitis classically entails acute onset of a sore throat with tonsillar exudate, fever, tender anterior cervical lymphadenopathy, and the absence of a cough and other likely signs of viral infection. A scarlatiniform rash, if present, is more specific for GAS, although a similar rash can be seen with *Arcanobacterium* infections. Streptococcal pharyngitis may also present in a manner indistinguishable from that of viral pharyngitis. Diphtheria is classically associated with the presence of a tightly adherent pharyngeal membrane (pseudomembrane) that attaches to respiratory surfaces. *Fusobacterium necrophorum* infection has been implicated in pharyngitis, especially in adolescents and young adults; *Fusobacterium* has also been associated with inflammation and thrombosis of the internal jugular vein, with eventual embolization of the infected thrombus, a symptom complex called *Lemierre syndrome*.

Complications

The occasional complications of viral infections associated with pharyngitis usually are caused by systemic manifestations of the infections or secondary bacterial infections such as sinusitis, otitis media, or pneumonia. GAS pharyngitis can produce suppurative and nonsuppurative complications. Displacement of either or both of the tonsils or asymmetric swelling of the soft tissues of the pharynx following pharyngitis should raise suspicion of a peritonsillar or pharyngeal abscess. Although GAS have often been associated with these soft tissue infections, oral anaerobic bacteria should also be considered in the differential diagnosis. GAS pharyngitis can also result in otitis media, sinusitis, and suppurative cervical adenitis. Other suppurative complications such as meningitis are rare.

Nonsuppurative complications of GAS pharyngitis include poststreptococcal acute glomerulonephritis (immunologic injury to the kidneys), acute rheumatic fever (immunologic damage to the heart valves), scarlet fever, streptococcal toxic shock syndrome, reactive arthritis, and pediatric autoimmune neuropsychiatric disorder associated with group A streptococci (PANDAS). Rheumatic fever is now rare in most developed countries outside of outbreaks, but it remains a significant issue in the developing world. Once affected, these patients require antimicrobial prophylaxis to prevent recurrent episodes of rheumatic fever and further damage to the heart tissue. Timely diagnosis and treatment of GAS pharyngitis is the best way to prevent the development of rheumatic fever.

Laboratory diagnosis

The primary goal of laboratory testing in most cases of acute pharyngitis is to differentiate streptococcal pharyngitis from viral pharyngitis. Testing for GAS is not recommended for children and adults with pharyngitis that is likely due to a viral cause based on clinical and epidemiologic clues. In addition, testing is not recommended for most children younger than 3 years of age in the absence of an epidemiologic contact given the rarity of infection in that population. For all other patients with clinical signs and symptoms suggestive of GAS infection, testing should be performed to avoid unnecessary antimicrobial therapy in those who are not infected with GAS given the overlap in clinical presentations. Clinical prediction scores such as the modified Centor score and the FeverPAIN score are often used to guide the decision to test. It is important to note that a positive test result does not definitively diagnose streptococcal pharyngitis because some patients are asymptomatically carriers of GAS but may have a concurrent viral illness causing the symptoms. Currently, there is no accurate method to distinguish these patients from those with true infection.

Throat culture for GAS is the diagnostic gold standard and has a sensitivity of 90% to 95%. In collecting pharyngeal specimens for streptococcal cultures (Fig. 32.2), it is important to adequately swab both of the tonsillar areas as well as the posterior pharynx. If any tonsillar exudate is seen, specific efforts should be made to directly swab involved areas. The tongue and other oral structures should be avoided with the swab to minimize contamination with oral biota and dilution of the specimen. After collecting the specimen, swabs should be placed in an appropriate transport medium and cultured on nonselective media, such as sheep blood agar, incubated

Fig. 32.2 Specimen collection from the oropharynx.

in ambient air or under anaerobic conditions. A selective medium can be added. The disadvantage of conventional culture, in contrast with rapid antigen testing, is the delay in obtaining results and the associated delay in therapy or a tendency to prescribe unnecessary empiric therapy, which might otherwise have been avoided.

Rapid antigen detection tests (RADTs) are point-of-care tests that most commonly use lateral flow enzyme immunoassays (EIAs) or optical immunoassays (OIAs) to identify GAS antigens. RADTs have excellent specificity; therefore therapeutic decisions can be made with confidence on the basis of a positive test result. The sensitivity of RADTs, however, is variable, ranging from 39% to 100% in individual studies. In children in whom the prevalence of GAS infection is higher and the risk of complications increased, it is recommended that a negative RADT result be followed up with a throat culture to avoid missing the diagnosis of GAS pharyngitis, unless the specific RADT used is sufficiently sensitive. In adults, a follow-up culture is generally not needed, given the lower incidence of GAS pharyngitis and the very low risk of developing complications, including acute rheumatic heart disease.

Serologic testing is not useful for the diagnosis of acute GAS infection but is helpful in confirming a recent streptococcal infection in cases of suspected poststreptococcal acute glomerulonephritis and acute rheumatic fever or during epidemiologic investigations. Atypical lymphocytosis and the presence of heterophile or specific IgG and IgM antibodies suggest EBV infection, and many other viruses may be detected with molecular assays (e.g., influenza virus, SARS-CoV-2). In cases of suspected acute HIV or bacterial infection, such as *N. gonorrhoeae* or *C. diphtheriae* infection, viral and bacterial polymerase chain reaction (PCR) assays should be performed.

Treatment

Treatment of viral pharyngitis is supportive, with the exceptions of influenza, HIV, and SARS-CoV-2, for which specific antiviral agents are available. Most cases of GAS pharyngitis are self-limiting, with resolution of symptoms in 3 to 4 days, even without antimicrobial therapy. Antimicrobials have been

shown to shorten the duration and, in some cases, reduce the severity of symptoms, although the effect is usually modest. Additional benefits of antimicrobial therapy include interruption of transmission of the infection to contacts and prevention of suppurative and nonsuppurative complications of GAS pharyngitis, including acute rheumatic fever. Antimicrobial therapy has not been demonstrated to prevent acute poststreptococcal glomerulonephritis. Antimicrobials should be prescribed only for episodes of proven GAS infection. Compared with reliance on clinical presentation alone, the availability of rapid testing has resulted in decreased inappropriate antimicrobial therapy for patients who likely have a viral illness; however, antimicrobials are still overprescribed for this indication.

Penicillin or amoxicillin is the drug of choice for GAS pharyngitis. Alternatives in penicillin-allergic patients include macrolides, clindamycin, and first-generation cephalosporins, depending on the specific type of allergy. Benefits of therapy for other non-GAS pharyngitis infections are uncertain. Performing a repeated throat culture or RADT after antimicrobial therapy for a test of cure is not necessary in most patients who have resolution of symptoms. The majority of patients who are asymptotically colonized with GAS do not require therapy because they generally have a low risk for developing symptomatic pharyngitis or immune-mediated complications or for transmitting infection to others. Some exceptions include a patient or close contact of a patient with a history of rheumatic fever, during rheumatic fever or poststreptococcal glomerulonephritis outbreaks, and if there are recurrent infections within a family. Patients who develop rheumatic fever warrant secondary prophylaxis to prevent subsequent GAS infections. The duration of prophylaxis depends on the clinical circumstance.

Sinusitis

Case study

A 40-year-old female patient presented to her health care provider complaining of fever and nasal discharge. She had developed cold symptoms 1 week earlier and was treating herself with over-the-counter medications, with little improvement. In fact, her symptoms had progressively worsened over the past 48 hours, with increasing headache and left facial pain. Her physical examination was notable for a low-grade fever, tenderness over the left maxillary sinus, and purulent drainage from the left side of the nose.

Epidemiology

Infectious sinusitis (or rhinosinusitis) is a common inflammatory reaction of the nose and paranasal sinuses, with approximately 30 million adults receiving a diagnosis annually. This chapter focuses on acute **sinusitis**, which is usually infectious in origin, rather than chronic sinusitis, which can have diverse causes. Cases of acute sinusitis are usually preceded by acute viral upper respiratory tract infections that occur predominantly in the winter and spring months. This disease entity is less common in children than in adults because of the incomplete development of most of the paranasal sinuses until adolescence.

Causes

Viruses, including rhinovirus, coronavirus, parainfluenza virus, adenovirus, and influenza virus, are the most common cause of acute sinusitis. Less than 2% of episodes of viral sinusitis in adults and 5% to 10% in children are thought to be complicated by bacterial infection. *S. pneumoniae* and *H. influenzae* are the bacterial pathogens historically identified as the most common causes of community-acquired infections in adults and children. *S. pyogenes*, *S. aureus*, and *M. catarrhalis* account for most of the remaining infections, the last being more common in children. In healthcare-associated infections, *S. aureus* and gram-negative bacilli are recovered more frequently.

Acute fungal sinusitis is uncommon in patients with an intact immune system; it occurs predominantly in immunosuppressed hosts treated with cytotoxic or immunosuppressive medications or in patients with uncontrolled diabetes mellitus (ketoacidosis). Respiratory allergies also predispose individuals to acute sinusitis. When recurrent infectious sinusitis is associated with recurrent pulmonary infection over prolonged periods, it suggests the possibility of cystic fibrosis, hypogammaglobulinemia, or ciliary dysfunction.

Pathogenesis

The sinuses normally undergo a continuous cleansing process through the action of ciliated epithelial cells. These ciliated cells move the mucus layer lining these areas toward the sinus ostia, the openings of the sinuses into the nasopharynx. This process normally clears the sinuses of bacteria from the adjacent nasopharynx. During acute rhinosinusitis, mucosal swelling can cause partial or complete obstruction of the sinus ostia, interrupting the flow of secretions and predisposing to bacterial overgrowth in the obstructed sinuses; this can occur with infectious and allergic causes. Viral infection and bacterial toxins can also alter the normal cleansing function of ciliated epithelial cells, and the mucus layer can become more viscous because of the resulting inflammation, further impairing this process. Noninfectious obstructions can cause a similar problem, such as foreign bodies (including nasotracheal tubes), tumors, and congenital structural abnormalities of the nasopharynx.

Clinical manifestations

In young children, the only symptoms may be persistent rhinorrhea and cough, either directly after a viral upper respiratory tract infection or following a brief period of clinical improvement. In young children with signs and symptoms of persistent sinusitis, foreign bodies in the nose must always be considered.

In adults, sinusitis is clinically suspected when purulent nasal discharge is accompanied by nasal obstruction and/or facial pain or pressure; nonspecific symptoms, including cough, headache, and low-grade fever may also be present. It is often difficult to clinically differentiate patients with viral sinusitis from those with bacterial superinfection, an issue that contributes significantly to the inappropriate prescription of antimicrobial agents for this largely viral condition. Suggested criteria for the diagnosis of bacterial sinusitis include (1) persistent symptoms without reduction for more than 10 days; (2) severe symptoms (high-grade fever, purulent

Fig. 32.3 Computed tomography scan of the paranasal sinuses in a patient with normal maxillary sinuses (**A**) and a patient with bilateral maxillary sinusitis (**B**). **A**, The large (black) cavities on either side of the nasopharynx are the normal maxillary sinuses. Of note is the absence of thickening of the lining and the absence of any opacity within the cavity of the maxillary sinuses. **B**, The difference in the maxillary sinuses compared with the image in **A** is the presence of opacification in both maxillary sinuses. This opacification represents purulence and mucosal thickening within the sinuses. The maxillary sinus on the right side of the figure also demonstrates an air-fluid level (the relatively straight, horizontal line between the air-filled black space above and the gray, fluid-filled space below [arrow]) characteristic of acute, purulent sinusitis.

discharge, and facial pain) present for 3 to 4 days at the beginning of the illness; and (3) initial reduction followed by subsequent worsening of symptoms.

Imaging with plain radiography or computed tomography (CT) scanning is not routinely recommended for the diagnosis of uncomplicated acute sinusitis because abnormalities seen on these images are nonspecific. Many patients with viral upper respiratory tract infections will have abnormal findings. Even in true sinusitis, imaging results will not distinguish between viral and bacterial causes. CT scans may be helpful, however, in patients with persistent or recurrent symptoms to identify predisposing structural abnormalities, disease complications caused by the spread of infection, or an infectious source in immunocompromised patients who have no localizing symptoms (Fig. 32.3).

Case check 32.3

The presentation of acute sinusitis in older children and adults, as in the introductory Case in Point, is often that of a prolonged respiratory tract infection that evolves into a new set of symptoms, including fever, purulent nasal discharge, and facial pain. When the maxillary sinuses are involved, facial pain may be worse when leaning forward or when a jarring force is experienced, such as walking down stairs. Patients with maxillary sinusitis can also experience headache and pain perceived to come from the upper teeth. Fever is present in only about 50% of patients with acute sinusitis.

Complications

Extension of bacterial infection to adjacent areas or structures can cause complications, including orbital cellulitis, osteomyelitis (infection of the bone), meningitis, brain abscess, and cavernous sinus thrombosis. Orbital cellulitis or retroorbital abscesses can result from direct extension

of infection from adjacent sinuses to the area around and behind the eye. Protrusion of the eye (proptosis) or limitation of ocular movements should suggest the possibility of extension of the infection to the retroorbital space; this is a serious complication that requires rapid diagnosis and emergency management.

Extension of frontal sinusitis can cause cellulitis in the forehead area overlying these sinuses and osteomyelitis of the frontal bone, with associated subgaleal abscess, referred to as *Pott's puffy tumor*. Further extension of frontal sinusitis can cause an abscess of the frontal lobes of the brain. Extension of infection from other sinuses (e.g., ethmoid, sphenoid) can involve the central nervous system (CNS) in the form of meningitis or brain abscess. Suspicion of such severe complications must remain high in patients who appear to have refractory sinusitis in the setting of altered mental status or new neurologic complaints.

Laboratory diagnosis

The gold standard for the diagnosis of sinus infection is direct sinus puncture and aspiration. This invasive and potentially painful procedure is usually unnecessary, given the knowledge available of the common etiologic pathogens. Sinus aspirate culture should, however, be considered if there is a suspicion of intracranial extension of the infection, if empiric antimicrobial therapy has failed, or if the patient is severely ill or immunocompromised. These samples are inoculated onto culture media such as sheep blood, chocolate, and MacConkey agars, which are routinely used to isolate respiratory tract pathogens. Cultures of nasal secretions or of nasal swabs are unreliable indicators of the pathogens causing acute infection within the sinus and should not be routinely performed or used for clinical decision making. For patients in whom acute fungal sinusitis is suspected, an ear, nose, and throat (ENT) specialist should be consulted immediately for

examination, obtaining a specimen for culture and histopathology, and possible debridement.

Treatment

Symptoms of viral sinusitis resolve spontaneously in 1 to 2 weeks and do not require antibacterial therapy. Despite estimations of bacterial infections occurring in less than 10% of acute rhinosinusitis cases, more than 80% of patients with a diagnosis of acute sinusitis are prescribed antimicrobial therapy, most of which is inappropriate. Antimicrobial therapy should be considered if bacterial infection is suspected based on the criteria discussed earlier (see the "Clinical Manifestations" section). For those patients with persistent symptoms that have not worsened and are not severe, some guidelines give an option to observe and reevaluate in 3 days versus prescribing antimicrobials at the initial visit.

The agent of choice in the absence of risk factors for antimicrobial resistance (e.g., age <2 or >65 years, daycare attendance, recent antimicrobial therapy, recent hospitalization, comorbidities, immunocompromised state), severe infection, or high endemic rates of penicillin-nonsusceptible *S. pneumoniae* is amoxicillin for both adults and children. If any of the previously mentioned conditions are present, amoxicillin-clavulanate is recommended. Alternatives in penicillin-allergic patients or in patients in whom treatment has failed include fluoroquinolones or doxycycline in adults and a third-generation cephalosporin plus clindamycin in children. Macrolides should be avoided because of high rates of resistance in *S. pneumoniae*. As an adjunctive therapy, intranasal corticosteroids can be beneficial for symptomatic relief in patients with a history of allergic or chronic rhinitis. Patients with healthcare-associated sinusitis may require broader-spectrum initial therapy. Patients with acute invasive fungal sinusitis require aggressive debridement and directed antifungal therapy.

Otitis media

Epidemiology

Acute otitis media (AOM), an infection of the middle ear, is the most common bacterial infection in children and one of the most prevalent reasons for visits to the pediatrician. Peak incidence is seen in children between 3 and 24 months of age, and most children have had at least one episode of AOM by 3 years of age. Identified risk factors include a history of AOM, attendance at a daycare center, family predisposition for AOM, exposure to passive tobacco smoke, nasopharyngeal colonization with otopathogens, and presence of anatomic nasopharyngeal disorders.

After the introduction of a 7-valent pneumococcal conjugate vaccine (PCV7) aimed at reducing invasive pneumococcal disease in 2000 and a 13-valent pneumococcal conjugate vaccine (PCV13) in 2010, there was an overall reduction in rates of AOM in the United States, especially cases caused by *S. pneumoniae*, including penicillin- and ceftriaxone-resistant strains. However, non-vaccine-type pneumococcal strains and other pathogens continue to cause disease. In addition, AOM is the most common childhood indication for which antimicrobial agents are prescribed, which is of significant

importance in the current era of multidrug-resistant (MDR) and pan-resistant bacteria, in which there is an urgency to reduce unnecessary antimicrobial use. The introduction of an "observation" option for selected children (see "Treatment" section later) has reduced antimicrobial prescriptions for this entity.

Many aspects of AOM parallel those of acute sinusitis, which is not surprising given the proximate locations of these infections and a similar pathogenesis, including preceding viral infection. In older children and adults, the syndrome of middle ear infection, although less common, is still a major precipitant of outpatient office visits during the winter and spring seasons, when viral respiratory infections are common.

Causes

As is the case for acute bacterial sinusitis, viral infections play a pivotal role in the pathogenesis of AOM, preceding bacterial infection in most cases. It is therefore not surprising that viruses have been isolated from the middle ear in some cases. Adenoviruses, rhinoviruses, coronaviruses, respiratory syncytial virus (RSV), influenza virus, and human bocaviruses, among others, have all been recovered from cultures; RSV seems to be particularly associated with AOM.

The microbial cause of the typical case of AOM has been clearly defined by cultures of infected middle ear specimens obtained by direct aspiration from the area. Despite the use of the PCV7 and PCV13, *S. pneumoniae* still accounts for a significant proportion of isolates, likely at least in part because of increasing infections with non-vaccine-type strains. Nontypeable *H. influenzae* and *M. catarrhalis* are other common bacterial pathogens; importantly, both of these can produce β -lactamase, which can affect treatment efficacy. *S. pyogenes* and *S. aureus* have also been implicated in this disease. In patients who have received multiple courses of broad-spectrum antimicrobials for AOM or other infections, have tympanic membrane perforations, or have severe underlying comorbidities or immunosuppression, AOM is more likely to be caused by gram-negative pathogens.

Pathogenesis

The pathogenesis of AOM is similar to that of acute bacterial sinusitis in that a viral upper respiratory tract infection generally precedes or occurs concurrently with most cases of AOM; infection is established when there is subsequent impairment of the normal host defense and drainage mechanisms. The middle ear and eustachian tube, the canal that links the middle ear to the nasopharynx, are lined with ciliated epithelium and mucus-secreting cells. These cells function to prevent infection through the clearance of contaminating infectious agents, thereby inhibiting the passage of bacteria from the nasopharynx to the middle ear cavity. Viral infection impairs this function and can cause mucosal edema, leading to eustachian tube dysfunction and obstruction and development of negative pressure within the middle ear cavity with subsequent entrance of bacteria colonizing the nasopharynx and development of suppurative infection.

In younger children, the eustachian tube is shorter and travels a more direct course from the nasopharynx to the

middle ear, and thus predisposes to easier contamination of the middle ear with nasopharyngeal bacteria. The higher incidence of viral infections in younger children also likely contributes to the increased incidence of AOM in this age group. Suppurative infection can cause fluid buildup in the middle ear that, if prolonged, can affect hearing. In addition, in a small number of cases, infection can spread to adjacent structures.

Clinical manifestations

The diagnosis of AOM is based on signs, symptoms, and direct examination of the tympanic membrane of the ear. Whereas ear pain is the classic symptom of AOM, early signs and symptoms may not be localized, especially in young children. In these cases, fever and irritability may be the only signs of illness. In older children, tugging at the involved ear may be noticed during or at the end of the course of an upper respiratory tract infection. Changes in hearing and, late in the course of infection, drainage of purulent secretions from the ear canal can be associated with perforation of the tympanic membrane. Examination of the tympanic membrane itself classically shows a bulging erythematous or cloudy membrane caused by the presence of fluid, or an effusion, in the middle ear cavity. Pneumatic otoscopy shows decreased mobility of the membrane, consistent with the presence of fluid. In advanced cases, perforation of the membrane with otorrhea, or drainage from the ear, is present.

Complications

Progression of AOM can damage the tympanic membrane, resulting in perforation. Chronic middle ear effusions can also be an issue; in younger children, subsequent hearing loss can have adverse effects on speech development and education that is less of a consequence in adults.

Severe suppurative complications of AOM are rare. Acute mastoiditis, involving extension of the infection to the nearby mastoid air cells of the temporal bone, is an uncommon complication in the antimicrobial era. This can require surgical debridement or resection (mastoidectomy) in addition to antimicrobial therapy to prevent progressive disease. Local extension of infection and spread to the CNS is another serious but uncommon complication.

Laboratory diagnosis

Because of the invasiveness of direct aspiration of fluid from the middle ear and because the predominant pathogens for AOM are known, obtaining specimens for culture before initiating therapy is neither recommended nor necessary in most cases. If an unusual or drug-resistant organism is suspected or the patient fails to respond to empiric antimicrobial therapy, a direct culture of the middle ear fluid by tympanocentesis may be indicated. Culturing the nasopharynx is not helpful in identifying middle ear pathogens; a positive culture for typical otic bacterial pathogens has a low positive predictive value for isolation of the same organism from the middle ear. In addition, viral studies do not provide helpful information in individual cases because it is well known that viral infections precede bacterial AOM, and the presence of virus does not rule out a concomitant bacterial superinfection.

Treatment

The necessity of treating AOM, especially in older children, has been a matter of much debate and illustrates the competing priorities of preventing suppurative complications of the disease and the need for prudent antimicrobial prescribing in an era of MDR bacteria. The natural history of most cases of AOM is resolution of symptoms within a few days to 1 week without antimicrobial therapy. Immediate antimicrobial treatment is recommended in children at high-risk of complications including those younger than 6 months of age, those with severe or persistent symptoms, those with otorrhea, and children 6 to 23 months of age with bilateral nonsevere AOM. Close observation is recommended for others with close follow-up. Tympanostomy tube placement may be considered for recurrent AOM (at least three episodes in 6 months or four episodes in 1 year).

Adults are generally treated at diagnosis because of a lack of data regarding complications. If treatment is indicated, the initial drug of choice in most guidelines is amoxicillin, but in those with risk factors for resistant organisms (β -lactamase-producing *Haemophilus* or *Moraxella*) or those who fail to respond to this initial regimen, an alternative antimicrobial such as amoxicillin-clavulanate should be used. Preventive measures include vaccination for pneumococcus and influenza according to the schedule determined by the Advisory Committee on Immunization Practices (ACIP), encouraging exclusive breast-feeding for the first 6 months, and avoidance of tobacco smoke exposure.

Epiglottitis

Case study

A 4-year-old male patient who recently immigrated to the United States was brought to the pediatrician's office with a 6-hour history of fever and trouble swallowing. Inspiratory stridor was noted by the pediatrician. The patient was immediately taken to the hospital, where, after assurance of airway protection, the epiglottitis was visualized and noted to be red and edematous. He had not received routine childhood vaccinations.

Epidemiology

The epiglottitis is a cartilaginous structure positioned at the anterior aspect of the opening of the trachea whose function is to protect the airway from the aspiration of secretions and food during swallowing. Acute **epiglottitis** (often referred to as *supraglottitis* in adults) can be a rapidly progressive infection of this structure and of adjacent soft tissues in the upper airway, which can result in airway obstruction and respiratory failure, a life-threatening emergency.

Historically, epiglottitis was primarily a disease of children 2 to 7 years of age. However, the epidemiology of epiglottitis changed drastically with the introduction in 1987 of a vaccine for *H. influenzae* type b (Hib), the predominant pathogen causing childhood disease. Since that time, the incidence of epiglottitis in this age group has decreased dramatically, whereas rates in adults have not been significantly affected; older children and adults now form the majority of cases in many studies. Although an uncommon occurrence

in the average clinical practice, the potentially life-threatening nature of this infection warrants familiarity with this syndrome.

Causes

Today, epiglottitis is an uncommon disease. Despite widespread Hib vaccination, Hib is the most common cause of epiglottitis, occurring even in vaccinated individuals. However, the proportion of pathogens other than Hib causing this condition has increased and include, GAS, *S. pneumoniae*, staphylococci (including methicillin-resistant *S. aureus* [MRSA]), nontypeable *Haemophilus* spp., *Klebsiella* spp., and recently SARS-CoV-2. In addition, noninfectious causes, including chemical and thermal irritants, are in the differential diagnosis.

Pathogenesis

The soft tissues of the epiglottis and surrounding structures are susceptible to accumulation of edematous fluid during the inflammatory process incited by infection. Combined with the critical location of the epiglottis at the opening of the trachea, this creates the danger of partial or complete airway obstruction as the disease progresses. It is common, in adults particularly, to involve other structures in the supraglottic region, including the vallecula, arytenoids, and aryepiglottic folds, such that the term *supraglottitis* is often used in adult cases. Epiglottitis has also been linked to sudden infant death syndrome.

Clinical manifestations

In classic childhood cases, the hallmark of epiglottitis is the presence of severe sore throat and pain on swallowing (odynophagia) in the absence of signs of inflammation in the oropharynx on physical examination. The onset of symptoms is abrupt, and in children, a high-grade fever and a toxic appearance are common. Pain with swallowing can be so severe that patients have dysphagia and avoid swallowing secretions, resulting in the classic sign of drooling. Stridor, a high-pitched sound noted during breathing, indicates upper airway obstruction, which is a medical emergency. Adults commonly present in a more indolent fashion and, although sore throat and odynophagia remain common, stridor and respiratory distress are seen much less often. This is likely in part caused by their larger diameter airways, although the risk of airway obstruction still exists, especially with airway manipulation or instrumentation. Underlying patient comorbidities such as diabetes mellitus can increase the risk of severe disease.

The gold standard for diagnosis is direct visualization of the epiglottis with laryngoscopy. Because of the concern for the rapid development of airway compromise and subsequent respiratory failure, this should be done in a setting in which intubation or tracheostomy can be performed immediately to secure the airway, if necessary. Blood cultures and cultures of the epiglottis (only after the airway is secured) should be obtained, and intravenous (IV) antimicrobial therapy should be initiated immediately. A lateral neck x-ray has classically been described as having a thumbprint sign, representing a swollen, edematous epiglottis, but this is not sufficiently sensitive to rule out disease in its absence. The differential

diagnosis for epiglottitis in children includes other causes of airway obstruction, including croup (laryngotracheitis), bacterial tracheitis, and retropharyngeal abscess.

Croup is the most common cause of infectious airway obstruction in young children 6 months to 3 years of age; most cases are caused by viral infections, usually parainfluenza virus type 1 or 3. Swelling of the subglottic structures, larynx and trachea, is responsible for the symptoms. Although epiglottitis tends to have an abrupt onset of symptoms, croup tends to have a more insidious onset, with a viral prodrome of rhinorrhea, congestion, and a harsh barking cough. Like epiglottitis, patients may also present with stridor if upper airway obstruction is present.

Bacterial tracheitis, like epiglottitis, is uncommon and occurs primarily in young children. The most likely causative organisms include *S. aureus*, *S. pneumoniae* and other streptococci, and *M. catarrhalis*. Clinically, the disease starts with a viral prodrome similar to croup and then progresses to a more toxic appearance, with fever and respiratory distress, resembling epiglottitis. These patients develop subglottic edema and thick tracheal secretions.

Complications

The most important complication of epiglottitis is respiratory compromise progressing to respiratory failure because of airway obstruction from edema of the supraglottic structures. Other potential complications include the development of epiglottic abscess, necrotizing epiglottitis, pneumonia, and in patients who are bacteremic, meningitis and septic shock.

Laboratory diagnosis

Direct swab cultures from the area of the epiglottis are useful for establishing the causative diagnosis, but they should be taken only when the airway is secure. A direct smear of epiglottic exudates for microscopic examination may reveal numerous WBCs and pleomorphic, gram-negative bacilli characteristic of *H. influenzae* (Fig. 32.4). Blood cultures should be performed in all patients in whom epiglottitis is suspected. An enriched medium such as chocolate agar in an environment with an increased concentration of carbon dioxide (5% to 10%) is preferred when trying to isolate *Haemophilus* spp.

Fig. 32.4 Gram-stained smear of sputum-exudate with gram-negative coccobacilli suggestive of *Haemophilus* spp. (arrow).

Treatment

IV antimicrobials, such as third-generation cephalosporins (e.g., cefotaxime, ceftriaxone) or ampicillin-sulbactam, should be administered. Coverage for MRSA should be added when risk factors exist. If immediate airway securement is not required at the time of initial evaluation, patients should be monitored closely for signs and symptoms of respiratory distress, which might require subsequent urgent intubation or tracheostomy. IV corticosteroids have been given, theoretically to help reduce inflammation and swelling of the airway, although their efficacy has not been proven in research studies.

Case check 32.4

Epiglottitis, especially in children, can be a life-threatening emergency because of the risk of airway compromise. Any attempts to visualize or culture the supraglottic region should be performed only in a controlled setting where airway protection can be assured. Historically, *Haemophilus influenzae* type b (Hib) was responsible for the majority of cases. The rates of infection with this particular organism have drastically decreased since the introduction of childhood vaccination for Hib, but cases still occur, especially in unimmunized populations.

Pertussis

Epidemiology

Pertussis, commonly referred to as *whooping cough*, is a highly communicable respiratory illness in susceptible patient populations that is transmitted from person to person via aerosolized droplets. This infection usually occurs in infants and young children, and serious complications are seen more often in this age group. Following the introduction of the first pertussis vaccine in the 1940s, the incidence of pertussis significantly decreased. However, in the United States the disease incidence began increasing in 2010 reaching a 50-year high of 48,277 cases in 2012, after which case numbers began decreasing. During this surge, large outbreaks in several states with notable infant mortality and increased cases in the adolescent and adult population were reported. In 2022, the number of provisional cases for 2021 was 1609. Older adult patients can exhibit milder manifestations of the illness that can go undiagnosed and allow them to serve as reservoirs for transmission of the infection to susceptible children and others.

Causes

Bordetella pertussis and *Bordetella parapertussis* are the pathogens usually associated with pertussis; *Bordetella bronchiseptica* and *Bordetella holmesii* have been associated with a similar clinical syndrome. An important differential diagnosis in patients presenting with a pertussis-like syndrome is adenovirus infection (serotypes 1, 2, 3, and 5).

Pathogenesis

Although the pathogenesis of pertussis is incompletely understood, numerous studies suggest a significant role for pertussis toxin (PT), which interrupts the transduction of signals from cell surface receptors to intracellular systems. PT is included in all currently licensed acellular pertussis vaccines.

Another toxin is adenylate cyclase toxin that enters target cells and increases intracellular cyclic adenosine monophosphate (cAMP) levels, causing cell damage or cell death. Factors produced by these bacteria have been implicated in several stages in the disease process, including paralysis of the cilia of lower respiratory tract cells, damage to tracheal epithelial cells, impairment of host immunity, and induction of a systemic response to pertussis. During the paroxysmal phase of the illness, when patients develop the characteristic whooping cough, the clinical signs and symptoms are attributed to toxins elaborated by the organisms. It is apparent that pertussis is not a disease caused by the effects of a single toxin, as is the case in some other bacterial infections. Rather, the clinical syndrome is probably the manifestation of the cumulative effects of several toxins produced by the pathogen and the related host inflammatory response.

Clinical manifestations

In the initial catarrhal phase of the illness, the symptoms of pertussis are similar to those of a viral upper respiratory tract infection, with mild cough, conjunctival injection, and coryza (nasal congestion and discharge), making the differential diagnosis difficult for the first 1 to 2 weeks. Fever is uncommon or low grade throughout the course of the illness unless a secondary bacterial infection has occurred. The 2- to 4-week paroxysmal phase follows and is typically manifested by exhausting paroxysms of coughing, often with multiple coughs during one expiratory cycle and a characteristic whooping sound at the conclusion caused by forceful inspiration through a narrowed airway. Infants may develop apneic episodes rather than a whooping sound. Posttussive vomiting or syncope is not uncommon because of the severity of coughing. Symptoms are often worse at night. The final convalescent stage may last for several more weeks and comprises a chronic cough.

Complications

Severe infections requiring hospitalization occur most commonly in infants, especially those younger than 2 months of age. Older adults have increased rates of hospitalization compared with other age groups as well. The most common complication is pneumonia, which is seen in up to 20% of cases. This is usually caused by secondary infections with other bacteria, although *B. pertussis* infection itself can cause lower respiratory tract infection. Encephalopathy and seizures are seen in a small fraction of cases but can have serious consequences. In a minority of cases, pertussis can result in death, overwhelmingly as a consequence of pneumonia in young, unvaccinated children or older adult patients with underlying comorbid conditions, such as chronic pulmonary disease.

Many of the complications associated with pertussis are a result of the severe and forceful coughing episodes that occur, including pneumothorax, subconjunctival (and other superficial) hemorrhages, epistaxis (nosebleed), rupture of the diaphragm, umbilical and inguinal hernias, and rectal prolapse. This infection has been implicated as a cause of bronchiectasis later in life.

Laboratory diagnosis

A complete blood count (CBC) may show lymphocytosis, which is a reaction to PT, and has been associated with poor

outcomes in infected infants. Isolation of *B. pertussis* in culture from nasopharyngeal secretions is the historic gold standard for diagnosis and exhibits high specificity. However, culture recovery of *B. pertussis* can be difficult; sensitivity depends on the timing of the culture relative to disease onset, administration of antimicrobials before culture, and proper specimen collection and processing. Specimens should be collected from the posterior nasopharynx early in the course of disease (preferably within the first 2 weeks of onset of cough) and should be plated directly onto selective media, such as Bordet-Gengou or Regan-Lowe (RL) medium for optimal recovery. If direct inoculation is not possible, a transport medium such as RL transport medium should be used.

Because of the time delay in obtaining culture results and the inherent difficulties in culture recovery, culture has largely been superseded in clinical practice by PCR assay. PCR has the advantage of increased sensitivity compared with culture when used in the proper clinical situation, including in patients in whom antimicrobial therapy has already been initiated, which may result in false-negative culture results. As with culture, specimen testing is best done during the first few weeks of illness. PCR testing should be used only for patients with signs and symptoms suggestive of pertussis and should not be used for testing of contacts. The development of multiplex PCR has allowed detection of multiple related pathogens with one test; as such, *B. pertussis* testing may occur in the context of testing for multiple respiratory pathogens at once. Direct fluorescent antibody (DFA) testing has been used as a complementary method but is not recommended because of poor sensitivity and specificity.

Serologic testing may be helpful 2 to 12 weeks after the onset of cough, when culture and PCR results are more likely to be negative, and it is more useful for outbreak investigation. Several EIAs and bead-based assays are available to detect IgG or IgA antibody response to many different antigens. The recommended diagnostic assay is quantifying anti-PT antibody. Serologic measurements should be paired and obtained 2 to 4 weeks apart to assess the patient for a fourfold increase in titer to establish the diagnosis.

Treatment

Antimicrobial therapy often does little to help with symptom resolution unless given early in the course of the illness, but therapy plays an important public health role in minimizing the spread of infection. The macrolide class of antibiotics, including azithromycin and clarithromycin, is the therapy of choice; trimethoprim-sulfamethoxazole is an alternative. Droplet isolation precautions should be applied for hospitalized patients until 5 days after initiation of appropriate antimicrobial therapy. Given the often very high secondary attack rates, the same agents are also recommended as chemoprophylaxis for those who have had close contact with a patient with pertussis in the first few weeks of disease, regardless of pertussis vaccination status.

Vaccination against pertussis has been shown to prevent disease in many recipients and decrease the severity of illness in infected young infants whose mothers were vaccinated during the third trimester of pregnancy. Rates of vaccination of infants and young children with DTaP (diphtheria toxoid, tetanus toxoid, and acellular pertussis) vaccine remain high, but adolescents and adults are at risk because of their

waning immunity. Starting in 2005, the ACIP recommended the use of a DTaP vaccine to boost immunity in adolescents and adults including all pregnant women between 27 and 36 weeks' gestation; unfortunately, the vaccination rate among adults 19 years of age and older was only around 23% in 2015 and 32% in 2017. In 2019, among the 4674 patients 6 months to 6 years of age diagnosed with pertussis, only 37% had received three or more doses of DTaP. In 2020, the Centers for Disease Control and Prevention reported a substantial decline in DTaP vaccination in children during the COVID-19 pandemic—15.7% among children younger than 24 months and 60.3% among children aged 2 years to 8 years.

Lower respiratory tract infections

Infections in the lower respiratory tract usually occur when infecting organisms reach the lower airways or pulmonary parenchyma via bypassing the mechanical and other nonspecific barriers of the upper respiratory tract. Infections may result from inhalation of infectious aerosols, aspiration of oral or gastric contents, or hematogenous spread.

A series of host defenses must be overcome before a potential pathogen can establish infection in the lower respiratory tract. The sequence of events is somewhat different for respiratory viruses than for bacterial pathogens. The progression of viral pathogens from the upper to the lower respiratory tract is a process that involves spread among adjacent cells and distant inoculation of susceptible cells by aspiration of infectious secretions and, to a lesser extent, by hematogenous transmission of the virus. Lung infections by bacterial pathogens usually occur via direct inoculation of organisms through aspiration from the upper respiratory tract. [Table 32.2](#) summarizes clinical syndromes encountered in the lower respiratory tract and their associated causative agents.

Bronchitis and bronchiolitis

Epidemiology

Acute **bronchitis** is an infection and inflammation of the bronchi without involvement of the lung parenchyma (pneumonia). Bronchitis can be viewed as the lower respiratory tract extension of many of the same viral infections that cause seasonal upper respiratory tract infections; in many cases, these syndromes represent a continuum of the same infection. The peak season for acute bronchitis is the winter months, which correlates with the period of peak incidence of these viral respiratory tract infections. Acute **bronchiolitis**, an infection and inflammation of the smaller bronchioles, is the most common lower respiratory tract infection in infants and is most often seen in children between 3 and 6 months of age.

Causes

Any of the respiratory viruses that cause upper respiratory tract infection can cause cough as a manifestation of acute bronchitis. During seasons when influenza virus is epidemic in the community, this respiratory pathogen is the most common cause of acute bronchitis in the general population. During nonepidemic periods, other respiratory viral

Table 32.2 Lower respiratory tract infections

Clinical syndrome	Causative agents	Specimen collection	Other
Bronchitis, bronchiolitis	<u>Most common</u> RSV Influenza virus <u>Less common</u> <i>Mycoplasma pneumoniae</i> <i>Chlamydia pneumoniae</i> <i>Bordetella pertussis</i>	Nasopharyngeal or lower respiratory tract sample if influenza or pertussis is suspected. RSV in select cases Diagnostic testing not indicated in uncomplicated cases	Viral PCR test Viral direct antigen detection Viral culture
Community-acquired pneumonia	Children: <u>Most common</u> RSV Influenza virus A, B Parainfluenza virus 1, 2, 3 Adenovirus <i>M. pneumoniae</i> <u>Less common</u> <i>Streptococcus pneumoniae</i> <i>Staphylococcus aureus</i> <i>Haemophilus influenzae</i> Group B <i>Streptococcus</i> (neonates) Adults: <u>Most common</u> <i>S. pneumoniae</i> <u>Less common</u> <i>M. pneumoniae</i> <i>H. influenzae</i> <i>C. pneumoniae</i> Respiratory viruses <i>Legionella pneumophila</i>	Deep expectorated sputum. pathogens such as rhinovirus, coronavirus, human metapneumovirus (hMPV), and parainfluenza virus are often identified. In populations of young military recruits, adenovirus infections were the primary cause of acute bronchitis before the use of adenovirus vaccine. Nonviral respiratory tract pathogens, including *M. pneumoniae*, *Chlamydia pneumoniae*, and *B. pertussis*, can also produce acute bronchitis. The clinical presentation of these infections may be indistinguishable from that of acute bronchitis caused by viral pathogens.

Bronchiolitis in infants is predominantly caused by RSV, which accounts for 41% to 83% of cases, primarily occurring in yearly epidemics during the winter months. It is the most common cause of serious lower respiratory tract infections in children. Rhinovirus is also identified in a significant number of cases. In up to 30% of bronchiolitis infections, more than one viral pathogen may be isolated; the clinical implications of this finding are unclear.

Pathogenesis

As noted, evidence almost always exists of an antecedent or coexistent upper respiratory tract infection in patients with acute bronchitis. The spread of these upper respiratory tract infections to the lower airways, manifested as acute bronchitis, represents infection and damage of respiratory epithelial cells by the same pathogens. The extent of destruction of the respiratory epithelium differs with the pathogen causing the illness. Viruses such as influenza virus and adenovirus are highly cytopathic and cause significant epithelial cell destruction; other viral infections such as rhinovirus infections cause

epithelial cell dysfunction without producing much cell destruction.

The inflammatory response, necrotic debris from epithelial cell destruction, bronchospasm, and edema of the lower respiratory tract also contribute to the airway abnormalities and symptoms in these infections. This potential for airway obstruction, air trapping, and increased airway resistance is especially important in bronchiolitis in infants. The resulting obliteration of the lumen of small airways appears to be the primary pathogenic mechanism causing lower respiratory tract symptoms. T-cell response is critical in controlling RSV infection such that immunocompromised infants with deficient cell-mediated immunity may have a more severe infection.

Clinical manifestations

Patients with acute bronchitis often begin their illness with a syndrome typical of a viral upper respiratory tract infection, including rhinorrhea and nasal congestion. Systemic symptoms such as diffuse myalgias, low-grade fevers, and fatigue associated with viremic illnesses may also be seen early in the course of infection. The hallmark of acute bronchitis is a cough that can persist for as long as 6 weeks. The amount of sputum produced with coughing differs; the color of the sputum produced does not reliably distinguish bacterial from viral bronchitis.

In addition to signs of an upper respiratory tract infection, acute bronchiolitis patients present with signs of lower respiratory tract airway obstruction, such as expiratory wheezing

and respiratory distress. Young infants may also experience apnea. A persistent cough is common. The median duration of symptoms is 2 weeks, but in some cases can be more prolonged, especially in immunocompromised individuals.

Complications

A complication in some patients with acute viral bronchitis is the development of a secondary bacterial infection, either bronchitis or pneumonia. These secondary bacterial infections of the lower respiratory tract are usually caused by the common pathogens found in community-acquired pneumonia (CAP), such as *S. pneumoniae* and *H. influenzae*, although other bacterial pathogens (e.g., *M. catarrhalis*, gram-negative bacilli) may be involved in select patient populations (e.g., patients with underlying respiratory diseases, hospitalized patients).

Severe bronchiolitis is more common in younger, especially premature, infants. Infants with chronic cardiac and pulmonary disease are also at increased risk. As is the case for bronchitis, secondary bacterial infections can also occur in a subset of bronchiolitis patients. Concurrent otitis media may also be present. Although bronchiolitis causes significant morbidity in many cases, overall mortality has remained low.

There is also speculation that certain viruses that cause acute bronchitis can cause bronchiectasis. This is an abnormality in which inadequate drainage of respiratory secretions results from airway wall destruction, dilation, and scarring associated with recurrent lower respiratory tract infections. Considering the cytopathic nature of some viral infections (e.g., influenza, adenovirus) that can cause acute bronchitis, the suggested association between these pathogens and long-term development of bronchiectasis is a reasonable assumption.

Laboratory diagnosis

Because most bronchitis infections are caused by viruses with no available directed therapy, diagnostic testing was not previously recommended in uncomplicated cases that follow the expected, self-limiting course unless there was another indication for testing. During the COVID-19 pandemic, however, many of these patients received viral diagnostic testing for epidemiologic purposes or to complement therapeutic decision making. In patients in whom there are signs of secondary bacterial bronchitis, pertussis is suspected, or pneumonia is a concern, diagnostic testing may be useful in guiding therapy. In cases of suspected influenza virus infection of the lower respiratory tract, identification of the virus in respiratory tract secretions may be useful in guiding early antiviral therapy. The test of choice for most viral pathogens currently is a PCR assay because viral cultures generally have low sensitivity.

For patients with RSV, routine diagnostic testing is not recommended; diagnosis should be based on history and physical examination. RSV testing by viral antigen or PCR assay is available if needed to aid in patient cohorting for infection control purposes during outbreaks. In patients with bronchiolitis, chest x-rays do not usually show typical signs of pneumonia and can range in appearance from a normal chest x-ray to one showing peribronchial thickening, hyperinflation, or patchy consolidation. In most typical clinical cases, routine chest radiography is therefore not recommended because it does not change treatment.

Treatment

Acute bronchitis is caused by viral infection more than 90% of the time and therefore should not be treated with antimicrobial therapy in most otherwise healthy individuals without concurrent pneumonia. Antimicrobial therapy has not been shown by systematic review to be beneficial in acute uncomplicated bronchitis, and there was a trend toward increased adverse events in the treatment group. Despite this, 70% of outpatient visits for acute bronchitis result in an antibacterial prescription. Anti-influenza therapy ideally should be started within 48 hours of onset of symptoms for it to have a significant effect on clinical outcome, but in hospitalized patients or those at high risk for complicated or severe disease, antiviral therapy is recommended even after this time. In secondary bacterial bronchitis and/or pneumonia, antimicrobial treatment regimens can be designed using the same approach used for acute bacterial pneumonia. Pertussis can be treated with macrolide therapy (see the "Pertussis" section earlier in this chapter).

Treatment of RSV infection is generally supportive, including maintenance of hydration and supplemental oxygen when necessary. Ribavirin resistance has not been noted. Studies of inhaled bronchodilators and nebulized hypertonic saline have not shown consistent results. Palivizumab, a monoclonal antibody, can be used for prophylaxis during the RSV season in children at highest risk for bronchiolitis complications.

Influenza

Epidemiology

Seasonal flu activity begins in late fall and continues into the early spring. Cases are more frequent in northern climates. During pandemics, however, cases can occur outside the typical season. Between 2010 and 2020, the Centers for Disease Control and Prevention (CDC) estimates 9 million to 41 million influenza cases occurred, resulting in 710,000 hospitalizations and 12,000 to 50,000 deaths annually.

Causes

Influenza is an acute illness caused by influenza A virus or influenza B virus. Influenza A viruses are categorized into subtypes based on two surface antigens: hemagglutinin (H) and neuraminidase (N). Influenza B viruses are categorized into lineages. Influenza A is responsible for pandemics.

Pathogenesis

Human influenza viruses continuously undergo a process of antigenic drift, whereby amino acid substitutions allow the virus to evade preexisting host immunity. This *antigenic drift* is responsible for annual worldwide outbreaks and occurs more commonly in influenza A viruses. Periodically, two strains of influenza A virus will combine genetic material, often in animals, and result in the generation of a new reassorted virus to which there is often little population (herd) immunity. This process of genetic reassortment is termed *antigenic shift*. If the new virus contains virulence factors that include efficient person-to-person transmission, a worldwide influenza outbreak, or pandemic, can occur, with the potential for increased morbidity and mortality. The influenza pandemics in 1957 and

1968 were caused by genetic reassortment between human influenza viruses and influenza viruses from birds. The novel H1N1 influenza pandemic in 2009 was caused by the reassortment of genetic elements of human, swine, and avian strains.

Clinical manifestations

Respiratory tract infection with systemic symptoms of fever, myalgias, and fatigue is the most classic manifestation of influenza, but some patients may present only with rhinorrhea and cough, similar to other upper respiratory tract viral infections. Most cases involve the upper respiratory tract, but pneumonia can occur as well, either secondary to direct effects of the virus itself or because of bacterial superinfection.

Complications

Young children, older adults, pregnant women, and patients with underlying comorbidities, including heart and lung disease, diabetes, renal disease, morbid obesity, and immunosuppression, are at increased risk for severe disease, which in some groups includes an increased risk of developing primary influenza pneumonia. Hospitalization rates are increased in young children and older adults, and mortality is generally highest in older adults. Influenza infection also predisposes patients to develop secondary bacterial pneumonia; bacterial pathogens commonly seen in this setting include *S. pneumoniae*, *S. aureus* (including community-associated strains of MRSA), and *H. influenzae*.

Diagnosis

Previously, during an influenza outbreak, acute febrile respiratory illnesses could be diagnosed as influenza with a relatively high degree of certainty by clinical criteria alone, and testing was not always necessary. However, during the COVID-19 pandemic, influenza cases could not be reliably differentiated from infections caused by SARS-CoV-2 or other respiratory viruses on clinical grounds, and there is increased emphasis on testing for treatment, infection control and prevention, and epidemiologic surveillance purposes.

Diagnosis is accomplished by the detection of virus, viral antigen, or viral nucleic acid in nasopharyngeal swabs, mid-turbinate nasal swabs, nasal washes or aspirates, combined nasal and throat swabs, sputum, or bronchoalveolar lavage specimens, depending on the assay. Isolation of the virus in culture is highly sensitive and specific but may take several days after inoculation and therefore is not commonly performed for clinical care. Antigen detection can be performed quickly with high specificity but is insufficiently sensitive to rule out influenza. Molecular assays such as reverse-transcription polymerase chain reaction (RT-PCR) are now the standard of care with high sensitivity and specificity, the ability to distinguish among influenza A subtypes, and a turnaround time in hours. Multiplex PCR assays that can also detect SARS-CoV-2 are increasingly being used. The diagnosis can also be established retrospectively by serologic methods; a fourfold or greater increase in antibody titers between serum specimens obtained during acute illness and convalescence approximately 2 to 4 weeks later is considered diagnostic but will not inform timely clinical management.

Treatment

The neuraminidase inhibitors oseltamivir, zanamivir, and peramivir and the cap-dependent endonuclease inhibitor baloxavir are recommended for the treatment of influenza depending on the age, clinical characteristics, and disease severity of the individual. Adamantane-based M2 inhibitors, such as amantadine, are no longer indicated for influenza treatment because of widespread resistance. In healthy patients, antiviral therapy should be started within 48 hours of symptom onset to decrease the duration of symptoms and prevent complications such as pneumonia; therapy can also be considered for those with high-risk close contacts. In patients who require hospitalization, those with severe or progressive illness, or those at risk of significant complications, antiviral therapy is indicated regardless of illness duration.

The best way to prevent influenza is by annual vaccination starting in the fall of each year. Vaccines are manufactured annually based on global virus surveillance data to allow inclusion in the vaccine of influenza A and influenza B strains that are most representative of those strains circulating worldwide. Influenza vaccination is recommended for all persons at least 6 months of age who do not have contraindications. Antiviral therapy can also be used for chemoprophylaxis before or after exposure to prevent development of disease for high-risk patients, such as those who have vaccine contraindications or expected poor vaccine efficacy (i.e., caused by severe immunosuppression). Antiviral chemoprophylaxis is also indicated for patients and staff as part of the management of institutional outbreaks.

Emerging viral respiratory tract infections: coronaviruses

A number of emerging viral respiratory tract infections have been seen in the past few decades including avian influenza strains, pandemic H1N1 influenza A, hMPV, and reemerging adenoviruses. However, novel human coronaviruses have arguably had the most wide-reaching global consequences and will be reviewed here.

Severe acute respiratory syndrome and Middle East respiratory syndrome

SARS, a viral pneumonia, is caused by SARS-CoV that was first recognized in southern China in late 2002. This virus was believed to be of animal origin and was identified in civets and bats. The CDC estimates that 8098 infections and 774 deaths were attributed to this outbreak until it was contained in China in 2004. Although the initial cases were identified in China and Hong Kong, the disease spread rapidly, and cases were seen in five continents. Human-to-human transmission (direct contact with respiratory secretions and spread via respiratory droplets) was the primary mode of spread, and it was commonly seen in health care facilities. Airborne transmission was also postulated in the case of superspreading events on commercial airplanes.

Middle East respiratory syndrome (MERS) is also a viral pneumonia caused by a coronavirus. MERS was first recognized in Saudi Arabia in 2012, and cases have since been reported in the United States, Europe, and Asia, all of which were associated with travel to the Arabian Peninsula or

contact with a patient with MERS coronavirus (MERS-CoV). Camels appear to serve as a reservoir of MERS-CoV, but most cases have resulted from person-to-person transmission. Differences between MERS and SARS are that MERS-CoV does not spread as easily among humans, MERS pneumonia commonly occurs in patients with preexisting chronic illnesses, and it has a higher mortality rate than SARS.

Recommended viral diagnostic studies for SARS and MERS include nucleic acid amplification tests (NAATs) such as RT-PCR. Diagnosis requires multiple different clinical specimens for confirmation; lower respiratory, nasopharyngeal, serum, and stool specimens are usually used depending on the infection. Because viral shedding peaks around day 5 to day 10, those with initial negative test results may be retested later in the course if an alternative diagnosis has not been found and a high suspicion for SARS or MERS remains. A biosafety level 3 laboratory is required for handling specimens to prevent infection in laboratory personnel. Currently no proven effective antiviral medication exists; supportive care with appropriate isolation to prevent transmission is critically important.

COVID-19

In December 2019, a cluster of viral pneumonia cases was reported in Wuhan, China. A novel human coronavirus was quickly identified as the cause, later to be named SARS-CoV-2; the disease was termed *coronavirus disease 2019* (COVID-19). The infection rapidly became endemic in China, and in March 2020, the World Health Organization (WHO) declared a global pandemic. As of July 2022, over 570 million cases and more than 6.3 million deaths have been reported worldwide. The virus undergoes mutations producing new variants that cause a surge in cases. Our understanding of the epidemiology, clinical manifestations, diagnosis, treatment, and prevention of this disease continues to rapidly evolve.

Like SARS-CoV and MERS-CoV, SARS-CoV-2 is a betacoronavirus. Transmission is thought to be primarily through exposure to large respiratory droplets, but airborne transmission has also been recognized; contact with contaminated objects and secretions/excretions is thought to play a lesser role. Unlike influenza, it was subsequently realized that many infected individuals are asymptomatic, and both asymptomatic and presymptomatic transmission are significant contributors to the spread of infection, making containment particularly challenging.

The clinical presentation includes a spectrum from asymptomatic infection to severe pneumonia with respiratory failure, acute respiratory distress syndrome (ARDS), and multisystem organ failure. Children of all ages can be infected but generally seem to have milder symptoms than adults, although severe disease does occur. Risk factors for severe disease include older age; obesity; diabetes; chronic lung, heart, or kidney disease; and immunocompromised state. For many who develop symptoms, the disease has a characteristic clinical decline in the second week after onset. In addition to respiratory symptoms such as cough and shortness of breath, typical flulike symptoms (fever, headache, muscle aches, fatigue) are common as are gastrointestinal (GI) manifestations including diarrhea. An altered sense of taste or smell may also be present. COVID-19 has also been associated with a coagulopathy.

Complications of COVID-19 infection are still incompletely understood. Respiratory failure and ARDS are the most common end organ complications, but many organ systems can be affected including renal, hepatic, cardiac, and neurologic. There is a growing body of literature that a subset of infected patients has prolonged symptomatology, even after initial recovery, referred to as *long COVID*. Multisystem inflammatory syndrome in children (MIS-C) is a constellation of symptoms that can include fever, GI complaints, rash including mucocutaneous involvement, dyspnea, headache, and lethargy among others. Hypotension, myocardial involvement, and elevated inflammatory markers are common. It is thought that the syndrome results from immune dysregulation (cytokine storm) that develops after acute infection with SARS-CoV-2 as many children have negative molecular testing but positive antibodies, suggesting recent infection. This syndrome can occur in older adult patients as well, usually in young to middle-age adults.

Accurate diagnostics for SARS-CoV-2 are critical as COVID-19 cannot reliably be differentiated from other infections based on clinical manifestations alone, and test results affect treatment, public health, and infection prevention and control decisions. Testing is generally recommended for all symptomatic individuals as well as for some asymptomatic individuals in cases in which exposure has occurred or results will affect personal protective equipment usage and isolation decisions. NAATs have become the standard assay. These are generally performed on a nasopharyngeal, midturbinate, or anterior nares swab sample; saliva testing is also available. Sensitivity is high, especially for laboratory-based tests, but false-negative results do occur. NAATs have the disadvantages of higher cost, longer turnaround times, and persistent detection of viral RNA when ongoing transmissibility is unlikely. Repeat testing is not recommended within 90 days of a prior positive NAAT. Viral antigen assays that can be performed at the point of care are easy to use and provide quick results. Sensitivity is generally higher in symptomatic patients at the peak of infection, but lower than for NAATs, especially in asymptomatic individuals.

Multiple commercial antibody tests are now available to detect antibodies to either the spike or nucleocapsid proteins of SARS-CoV-2 using varied technologies; performance may vary among assays. Antibodies are generally not present before 2 weeks after symptom onset and are not recommended for ruling out acute infection. Antibody testing may be helpful in symptomatic patients with a high clinical suspicion and repeatedly negative NAATs, ideally 3 to 4 weeks after symptom onset. Antibody testing also has a role in diagnosing MIS-C and epidemiologic seroprevalence studies. It should be remembered that vaccination against SARS-CoV-2 can also result in detectable antibodies against the spike protein. Immune protection cannot be inferred based on current antibody testing data.

Several COVID-19 therapies and treatment guidelines are now available. Therapies include the antiviral agents ritonavir-boosted nirmatrelvir (Paxlovid) and immunomodulators dexamethasone, baricitinib, and tocilizumab (a monoclonal antibody against the IL-6 receptor). Supportive therapy includes high-flow nasal canula oxygen, mechanical ventilation, and extracorporeal mechanical membrane oxygenation.

Prevention of SARS-CoV-2 infection with vaccination is thought by many to be critical to ending the pandemic.

Currently, the U.S. Food and Drug Administration (FDA) has granted Emergency Use Authorization for three vaccines in the United States, two of which use a novel messenger RNA platform that has been studied for decades but was never previously FDA approved. Current available data indicate excellent efficacy with minimal reports of serious adverse events; postapproval safety monitoring is ongoing. Further surveillance of vaccine efficacy in the face of newly discovered viral variants will also be important.

Acute pneumonia

The distinction between acute bronchitis and acute **pneumonia** may be subtle. The distinction depends on the extent of involvement of the lower respiratory tract with the infectious process. Patients who have bronchitis do not exhibit the physical, radiographic, and pathologic findings of pulmonary parenchymal involvement (fluid accumulation in the alveoli) outside the airways. This type of lung tissue involvement with the infectious process defines pneumonia.

Pneumonia can be subdivided into diagnostic categories based on the clinical setting, presentation of the illness, exposure to specific pathogens, and age and type of host infected. The importance of using such a strategy to make a presumptive determination of the infectious cause of pneumonia is evident when one considers the many possible pathogens that can cause this type of infection; Table 32.3 lists the most common causative agents of lower respiratory tract infections, stratified by age group. It is important to focus the clinical diagnosis on a subgroup of likely pathogens to allow the initiation of reasonable empiric therapy while awaiting a specific causative diagnosis by the microbiology laboratory. The highest incidence of CAP and hospital-acquired pneumonia (HAP) occurs in very young and very old patients. However, the types of causative agents most likely to cause pulmonary infections in these two groups are different. In infants and children, respiratory viruses cause most pneumonias; in older adults, bacterial pathogens are more likely to be implicated.

Community-acquired pneumonia

Epidemiology

CAP is one of the most common infections encountered in clinical practice and the leading cause of death from infection in persons older than 65 years of age. The onset of symptoms is in the community or within the first 2 days after hospital admission. Vaccination against *S. pneumoniae*, the most common bacterial pathogen in children and adults, has resulted in a decrease in invasive pneumococcal disease (e.g., bacteremia, meningitis) from vaccine serotypes as well as cases of pneumonia in both children and adults. Despite advances in diagnostics and therapeutics in recent years, mortality rates have remained unacceptably high.

Causes

The same viral pathogens that cause upper respiratory tract infections in the community during the winter months are detectable in over 70% of CAP cases in children. RSV is the most commonly identified cause of viral pneumonias in children, especially infants, in most communities. Although viruses have long been accepted as the responsible causative

Table 32.3 Most common pathogens of lower respiratory infections by age

Age	Cause
Neonates	Group B <i>Streptococcus</i> <i>Escherichia coli</i> <i>Listeria monocytogenes</i> Cytomegalovirus
Infants	Respiratory viruses (respiratory syncytial virus, parainfluenza virus type 3) <i>Streptococcus pneumoniae</i> <i>Bordetella pertussis</i> <i>Chlamydia trachomatis</i>
5 months–5 years	Respiratory viruses <i>S. pneumoniae</i> <i>Haemophilus influenzae</i> <i>Staphylococcus aureus</i> <i>Mycoplasma pneumoniae</i> <i>Mycobacterium tuberculosis</i>
5 years–18 years	<i>M. pneumoniae</i> <i>S. pneumoniae</i> <i>Chlamydia pneumoniae</i> <i>M. tuberculosis</i>
Young adults (18 years–45 years)	<i>S. pneumoniae</i> <i>S. aureus</i> <i>H. influenzae</i> (type b and nontypeable) <i>C. pneumoniae</i> <i>M. pneumoniae</i> <i>M. tuberculosis</i>
Older adults	<i>S. pneumoniae</i> <i>H. influenzae</i> (type b and nontypeable) <i>M. pneumoniae</i> <i>Legionella</i> spp. <i>M. tuberculosis</i>
Institutionalized adults	Gram-negative bacilli, including Enterobacteriales, <i>Pseudomonas</i> , and <i>Acinetobacter</i> <i>S. aureus</i> <i>S. pneumoniae</i>

agent in many cases of pediatric pneumonia, a new appreciation for their role in adult CAP is evolving in large part because of advanced molecular diagnostic techniques that allow rapid and sensitive virus detection. Viruses were identified in more than 25% of adult pneumonia cases in one multicenter study. Influenza virus can cause primary viral pneumonia, be associated with subsequent bacterial superinfection (i.e., *S. pneumoniae* and *S. aureus*, secondary bacterial pneumonia), or lead to a mixed viral-bacterial pneumonia. Parainfluenza viruses 1 to 3, rhinoviruses, coronaviruses including SARS-CoV-2, hMPV, and adenoviruses are also frequently detected.

The most common bacterial cause of CAP in children and adults is *S. pneumoniae*. Although invasive pneumococcal disease with vaccine serotypes has decreased in children since the introduction of PCV7 and later with PCV13, many studies have demonstrated increased infections with non-vaccine serotypes. In the United States, the proportion of bacterial pneumonias in adults caused by *S. pneumoniae* has decreased significantly since the pre-antibiotic era. In children, other common pathogens include nontypeable *H. influenzae*, *M. catarrhalis*, and *M. pneumoniae*. In neonates, group B *Streptococcus* should be considered a potential pathogen.

In adult patients, *H. influenzae*, *M. catarrhalis*, and atypical pathogens such as *M. pneumoniae*, *C. pneumoniae*, and *Legionella* should also be considered. Patients with chronic lung disease can become infected with *H. influenzae*. *Legionella* more commonly affects older adult patients and those with immunocompromising and underlying comorbidities; the reported incidence has been increasing. Patients with a recent influenza virus infection are at increased risk of developing secondary bacterial pneumonia caused by *S. aureus* or *S. pneumoniae*.

The term *healthcare-associated pneumonia* (HCAP), as defined by the American Thoracic Society and Infectious Diseases Society of America, occurs after 2 or more days in a hospital or health care facility. Patients with HCAP are typically of older age and are infected with MDR organisms such as MRSA and gram-negative bacteria including *P. aeruginosa*. However, studies have not demonstrated the ability of these healthcare-associated risk factors to predict infections with MDR organisms, which appear to be more strongly linked with individual patient comorbidities. It is recommended that individual risk factors for MDR organisms be validated locally and used to guide antimicrobial selection.

Although *S. aureus* accounts for only a small percentage of cases of CAP, these infections deserve special attention because of a high mortality rate. Historically, most patients with *S. aureus* pneumonia were older and had serious underlying disorders such as cardiovascular disease, chronic pulmonary disease, diabetes, or cancer, and strains of MRSA were usually hospital-acquired. However, in recent years, a syndrome of necrotizing pneumonia with pulmonary hemorrhage has been associated with MRSA isolates that produce the Panton-Valentine leukocidin cytotoxin. Interestingly, these strains are often community acquired and can occur in young and otherwise healthy individuals, leading to significant morbidity and mortality.

Endemic mycoses, including histoplasmosis, blastomycosis, and coccidioidomycosis, can also cause acute pneumonia syndromes that may be indistinguishable from a typical bacterial community-acquired pulmonary infection. These infections may go unrecognized in many cases that self-resolve or may be diagnosed only when chronic, progressive, or disseminated disease is present despite antibacterial therapy.

Pathogenesis

It is now realized that the lung is not a sterile site as previously thought; a disruption in the balance of microbes can lead to pneumonia. In cases in which a new pathogen is introduced, bacteria from the oropharynx or GI tract gain access to the lower airways through aspiration. Normally, the defense mechanisms of the lung, including the ciliated epithelial cells and innate immune system phagocytic cells, can clear aspirated bacteria before imbalance in the normal ecosystem develops and infection is established. However, infection of the lower respiratory tract could develop if the bacteria involved are particularly virulent, the inoculum of inhaled microorganisms is high, or the immune system has been compromised. Other mechanisms can include local extension from a contiguous source of infection or hematogenous spread from a remote source of infection. Host variables that can contribute to the likelihood of aspiration and development of pneumonia include an impaired level of consciousness, underlying chronic lung disease, and receipt of immunosuppressive therapy.

Clinical manifestations

The clinical presentation of typical bacterial CAP (e.g., *S. pneumoniae*) in adults differs with the age and immunologic status of the host. Most patients with bacterial pneumonia note a relatively sudden onset of fever associated with chills. Cough producing purulent sputum that may be blood-tinged is typical. Chest examination and x-rays often show a localized area of lung involvement, described as lobar consolidation (Fig. 32.5). This abnormality in the lung tissue may be associated with hypoxia as measured by arterial blood gas monitoring, depending on the extent of lung involvement and existence of underlying lung disease. Routine laboratory studies will usually show an increased WBC count and neutrophilia with an increased percentage of immature forms of granulocytes (termed a *left shift*).

In older or immunocompromised patients, the clinical presentation of acute bacterial pneumonia may be less impressive than in patients who can mount a normal immune response to pulmonary bacterial infection. These immunologically compromised patients may have few respiratory tract

Fig. 32.5 Chest x-rays before (A) and after (B) development of an acute, community-acquired, pneumococcal pneumonia. The patient is facing the reader. B, Consolidation of the upper lobe of the right lung is evidenced by the dense, whitish opacification of this lobe, which contrasts with the normal air (black) density of the remainder of the lung.

complaints and low-grade or no fever. Nonspecific symptoms such as weakness, loss of appetite, and confusion may be the only manifestations of a progressive pneumonia. It is important to maintain a high index of suspicion in these patients and to pursue changes in patterns of behavior routinely with complete evaluations to avoid missing the diagnosis of pneumonia.

Mycoplasma infections may include symptoms of upper respiratory tract infection, rashes, and hemolytic anemia. *Legionella* infections often present with confusion; GI symptoms, including abdominal pain and diarrhea; and a dearth of pulmonary localizing symptoms early on. Hyponatremia is often notable.

Complications

Common complications of CAP include **parapneumonic effusions** (PPEs), which is the accumulation of fluid in the pleural space caused by inflammation from parenchymal lung infection. PPEs occur frequently in the setting of CAP; those that are less severe resolve with antimicrobial therapy. However, if appropriate therapy is delayed, PPEs risk becoming overtly infected, resulting in the formation of empyemas, collections of purulent fluid in the pleural space that require drainage (see the “Empyema” section later in this chapter).

CAP can also result in respiratory failure, including the need for mechanical ventilation; ARDS; and septic shock with multisystem organ failure. The mortality rate for CAP depends on the severity of disease; some studies have found mortality rates in excess of 20% in patients with severe disease. Patients with CAP have higher rates of long-term mortality as well, likely in part as a result of increased cardiovascular complications. A minority of *M. pneumoniae* atypical pneumonia cases result in encephalitis.

Laboratory diagnosis

For patients with mild disease who are managed as outpatients, microbiological diagnostic tests are generally not performed. However, during the COVID-19 pandemic, SARS-CoV-2 testing may be an exception because of the public health implications. Lower respiratory secretions and

blood cultures are recommended for those who are hospitalized and have severe CAP or who have risk factors for infection with MRSA or *P. aeruginosa* (including prior positive cultures and recent hospitalization and IV antimicrobial therapy). For patients who do not require mechanical ventilation, expectorated sputum cultures are easiest to obtain and the least invasive. These sputum cultures are often problematic because sputum expectorated from the lower airways must pass through the upper airway, which is colonized with many bacteria; this can interfere with isolation of the true pathogens and make interpretation of the results difficult. It is often recommended that these cultures be screened to ensure that they have no more than 10 squamous epithelial cells and at least 25 polymorphonuclear cells per low-power field to ensure that the sample is acceptable (Fig. 32.6); samples containing more than 25 squamous epithelial cells per low-power field (Fig. 32.7A) should not be cultured. Cultures obtained from secretions suctioned from a tracheal tube in ventilated patients have many of the same issues because endotracheal tubes and tracheostomies are frequently colonized with bacteria that may be irrelevant for the diagnosis of lower respiratory tract infection.

Fig. 32.6 Gram-stained smear of sputum acceptable for culture, with white blood cells and gram-positive diplococci suggestive of *Streptococcus pneumoniae*.

Fig. 32.7 **A**, Expectorated sputum. The Gram-stained smear is visualized with light microscopy under low-power view. There are no white blood cells, but there is a heavy presence of contaminating bacteria and epithelial cells. The sample is saliva, not sputum. There could be several reasons for submission of this sample to the laboratory. The patient could have been poorly directed and simply spit into the collection container, or the patient's cough may not have been productive of sputum. **B**, Aspirated sputum. The Gram-stained smear is visualized with light microscopy under high-power view. There are no white blood cells or organisms. However, it shows specialized cells and mucus (pink-stained background), which are the local materials from the surface of the tracheobronchial tree. This smear confirms that sputum was sampled and that there is no suspicion for infection and no evidence of significant contamination (e.g., large numbers of epithelial cells, commonly found in the mouth). Routine bacterial culture of this specimen might still grow insignificant oral biota or pathogens.

Other more invasive methods of obtaining lower respiratory tract samples include tracheal needle aspiration, which is rarely used because of its invasive nature, risk of complications, and poor acceptability by patients. Bronchoscopic methods are commonly used for patients who require mechanical ventilation as well as in cases of refractory or recurrent pneumonia, when the success of empiric therapy is in doubt. Cultures obtained by these more invasive methods also do not have 100% specificity because upper airway contamination can still occur during specimen collection. Many authorities have recommended a quantitative approach to cultures in which a threshold amount of growth must be present with each of these methods to predict causality of the bacterial growth detected. Quantitation does not apply to certain agents that are considered pathogenic when isolated at any concentration, including *M. tuberculosis*, *Legionella*, certain fungi, and agents of bioterrorism (see later).

In addition to issues of specificity in identifying a true pathogen, sensitivity is also an issue for any of these culture methods. Common pathogens, such as *S. pneumoniae*, are intrinsically difficult to culture, and pretreatment with antimicrobial agents can render cultures falsely negative. *Legionella* cases can also be challenging to diagnose because culture of the organism from sputum or a bronchial aspirate specimen requires special media, and *Legionella* spp. do not stain well with the Gram stain (Fig. 32.8).

Molecular diagnostic tools such as bacterial multiplex PCR assays have been used to identify pathogens in cases in which cultures are otherwise negative and to provide rapid test results to allow better targeting of therapy. Although sensitivity is significantly increased, a PCR has the same problems with specificity, and results must be interpreted in the context of the individual patient to determine whether a true pathogen was detected or if the result represents asymptomatic colonization. In many cases, multiplex molecular assays identify multiple pathogens in the same specimen that may be of uncertain significance.

S. pneumoniae characteristically produces α -hemolytic colonies on sheep blood agar. Biochemical tests, such as bile solubility and optochin sensitivity, can distinguish *S. pneumoniae* from other α -hemolytic streptococci. Cultures from blood and pleural fluid also can indicate the cause of pneumonia. Many adults with pneumococcal pneumonia also have positive blood

cultures (Fig. 32.9); this is less common in children. Adjunctive tests are available for many pathogens. Urinary antigen testing, which is noninvasive and relatively quick to perform, is commercially available for *S. pneumoniae* and *Legionella pneumophila*. Urinary antigen testing for *L. pneumophila* detects only serogroup 1; however, this accounts for the majority of community-acquired cases. Urinary antigen testing is recommended for both pathogens in severe CAP; testing for *Legionella* is also recommended in the setting of an outbreak or recent travel. Both a urinary antigen and a lower respiratory culture or PCR for *Legionella* should be performed when this diagnosis is considered. Testing for *M. pneumoniae* and *C. pneumoniae* can be problematic; options include culture, serologic tests, and PCR assays. A nasal PCR assay for MRSA can facilitate discontinuing or withholding MRSA therapy when negative.

Excellent molecular diagnostics are now available for many commonly encountered respiratory viruses, often as part of a multiplex PCR panel. Testing with a rapid molecular assay to detect influenza is recommended during annual community outbreaks; testing for SARS-CoV-2 is currently also indicated in patients with respiratory illnesses. These tests have excellent sensitivity, but specificity is variable. The presence of a virus does not rule out a concurrent or superimposed bacterial infection, and the result of the viral PCR assay must be interpreted with respect to the clinical situation.

Treatment

An initial decision about management of CAP is whether the patient should be hospitalized or can be treated as an outpatient. Validated clinical prediction rules for prognosis such as the Pneumonia Severity Index (PSI) should be used in addition to an assessment of each patient's resources and clinical situation to determine whether admission is warranted.

Patient comorbidities and the likelihood of drug-resistant pathogens must be considered to determine appropriate empiric antimicrobial therapy. Outpatients without risk factors or comorbidities may be treated with macrolide antibiotics, doxycycline, or amoxicillin monotherapy. Outpatients with certain comorbidities and inpatients with nonsevere CAP are recommended to receive a β -lactam antibiotic plus either a macrolide or doxycycline or a respiratory fluoroquinolone alone. Inpatients with severe CAP can be treated with a β -lactam antibiotic in combination with either a macrolide or a respiratory fluoroquinolone. If locally validated

Fig. 32.8 Gram-stained smear of *Legionella* species taken from culture revealing thin, long filamentous, lightly stained, gram-negative bacilli.

Fig. 32.9 Gram-stained smear of *Streptococcus pneumoniae* isolated from the blood culture of a patient with pneumococcal pneumonia revealing gram-positive cocci and short chains.

risk factors for MRSA or *P. aeruginosa* are present, regimens should be adjusted to empirically cover these pathogens. If cultures obtained do not grow these organisms, antimicrobial therapy should be deescalated.

For young children, most cases of pneumonia are viral in origin, and routine antimicrobial therapy for all cases is not recommended. When antimicrobial agents are indicated, amoxicillin or ampicillin may be used if drug resistance is not a concern, and third-generation cephalosporins are used when significant resistance exists, the child is not fully immunized against Hib and *S. pneumoniae*, or the infection is severe. A macrolide is used alone or in addition to the β -lactam antibiotic when atypical pathogens are suspected in the outpatient and hospital settings, respectively.

A specific pathogen is never identified in the majority of cases, and treatment remains empiric; however, therapy should be pathogen-directed when possible. The duration of therapy depends in part on clinical improvement of the patient but is typically for a minimum of 5 days for uncomplicated adult infections; recommended courses in children may be longer.

Patients diagnosed with influenza A and influenza B pneumonia should be treated with antiviral therapy regardless of the duration of illness before diagnosis. As with many respiratory infections, prevention with vaccination is of critical importance. All individuals older than 6 months of age without contraindications should receive an annual influenza vaccine. Young children and older adults or adults with comorbidities should receive a pneumococcal vaccine. Age-appropriate vaccination for pertussis and Hib is also recommended. Vaccination against SARS-CoV-2 is now available.

Hospital-acquired and ventilator-associated pneumonias

Case study

A 60-year-old male patient with a history of emphysema and chronic bronchitis was admitted to the hospital to have his gallbladder removed. He was given perioperative antimicrobial prophylaxis with cefoxitin. Because of the patient's underlying lung disease, there was difficulty weaning him from the ventilator post-operatively. Seven days after surgery, he developed a high fever, increased secretions from his endotracheal tube, and an infiltrate in the lower lobe of the right lung, as detected on a chest x-ray.

HAP or nosocomial pneumonia is defined as pneumonia that is acquired 48 hours or more after hospital admission and is not associated with mechanical ventilation, whereas **ventilator-associated pneumonia (VAP)** is a pneumonia episode diagnosed at least 48 hours after airway intubation and initiation of mechanical ventilation.

Epidemiology

VAP is estimated to occur in approximately 10% of patients who require mechanical ventilation for longer than 48 hours, and it carries a substantial morbidity and mortality risk. VAP is associated with longer duration of mechanical ventilation, longer hospital stay, and increased health care costs. The all-cause mortality rate has been estimated between 20% and

50%; the attributable mortality in one meta-analysis was 13%. Although less data exist for HAP, it has been associated with significant complications as well.

Causes

The spectrum of pathogens associated with HAP differs from that of CAP. Because microaspiration of upper airway secretions is the most common route of pathogen entry into the lower respiratory tract, the cause of HAP depends largely on the types of organisms colonizing the oropharynx and possibly the GI tract. Patients with HAP are at greater risk for colonization and infection with a wider spectrum of MDR bacterial pathogens, such as MRSA, *P. aeruginosa*, Enterobacterales (e.g., *Enterobacter* spp., *Klebsiella* spp., and *E. coli*, including those producing extended-spectrum β -lactamases [ESBLs] and carbapenemases), and *Acinetobacter baumannii*. The spectrum of MDR pathogens is dynamic and may differ by geographic area, hospital, or specific unit within the hospital. The most consistently identified risk factor for MDR HAP/VAP is recent exposure to antimicrobial agents. The availability of current hospital epidemiologic data on MDR pathogens and their antimicrobial susceptibilities (termed a *cumulative antibiogram*) is essential in choosing appropriate empiric antimicrobial therapy. Mixed infections are common, although anaerobic infections are seen infrequently. Rates of hospital-acquired *L. pneumophila* infection differ considerably among hospitals but are generally lower than for community-acquired infection with this organism. Viruses may be responsible for up to 20% of HAP/VAP cases.

Pathogenesis

As with CAP, the pathogenesis of HAP is related to upper respiratory tract colonization, the number and virulence of organisms entering the lower airway, and the response of the host's defenses to this new introduction or imbalance in the normal lung microbiota. Older age, more severe underlying illness, previous treatment with antimicrobial agents, and manipulations that increase the gastric pH are all associated with increased oropharyngeal colonization with bacteria (Fig. 32.10). Such pathogens may be acquired from the patient's own GI tract, but exposure of patients to the microbial biota encountered during hospitalization provides an exogenous source of microbes that can also be involved in subsequent HAP. Hospitalized patients with altered levels of consciousness aspirate pharyngeal contents into the lung more often than normal volunteers. In addition, intubation of the lower airway greatly increases the risk of developing HAP by bypassing the normal mechanical defenses provided by the glottis and cough reflex. Nasogastric intubation also increases the risk of aspiration resulting from interference with glottic function and increased reflux of gastric secretions into the oropharynx.

Clinical manifestations

Diagnosing HAPs is often challenging. Several noninfectious processes can affect the lungs and cause many of the same clinical signs and symptoms and chest radiographic findings that are seen with pneumonia, making differentiation difficult. A generally agreed-on definition using clinical criteria in many guidelines is a new or persistent infiltrate on chest imaging accompanied by any of the following: fever, elevated or depressed WBC count, increased

Fig. 32.10 Gram stain of gram-negative bacilli in a tracheal aspirate (the arrow indicates an intracellular gram-negative bacillus). They are common pathogens in hospital-acquired pneumonia. (Courtesy Dr. William M. Janda.)

oxygen requirements, and production of purulent sputum. Unfortunately, all of these findings are relatively nonspecific. Some definitions may also include microbiologic data as a criterion.

Complications

Patients with extensive viral or bacterial pneumonias may have insufficient ventilation to the involved lung to adequately support respiration. In rapidly progressive, multilobar pneumonias, ventilatory support may be needed as a result of overwhelming infection or an injury response of the lung, known as *ARDS*. In these cases, mechanical support of ventilation and other supportive measures are used to provide time for antimicrobial therapy to control the pneumonia and allow recovery of lung function. An example of tissue destruction caused by pneumonia is the development of a lung abscess. In this case, the pulmonary infection results in destruction of the lung parenchyma in the area of a necrotizing bacterial infection. These infections usually can be treated with antimicrobial therapy alone. If the abscess is large and refractory to therapy, surgery may be required. As in CAP, empyemas can also occur.

Extension of the infection beyond the chest usually occurs when bacteria invade the bloodstream (bacteremia). The same type of systemic spread is possible with viral pneumonias (viremia), although the consequences of viremia are usually much less severe than those of bacteremia. Patients with bacteremia as a complication of pneumonia have increased mortality compared with patients with pneumonia without bacteremia. In some cases, this may simply reflect the bacterial burden and the difficulty in controlling the infection. In other cases, such as gram-negative bacillary bacteremia, the presence of bacteria and their constituents (e.g., endotoxin) may be associated with severe shock, further complicating care of the patient and increasing the likelihood of a fatal outcome. In addition to the direct consequences of bacteremia, in some cases, an infection originally established in the lung can spread via the bloodstream to other sites, such as the CNS, a so-called *metastatic infection*.

Laboratory diagnosis

Many of the same principles for microbiologic diagnosis of CAP apply to HAP. Current guidelines for HAP and VAP recommend noninvasive, semi-quantitative sampling (i.e., expectorated sputum or endotracheal aspiration culture) for diagnosis of the potential pathogen rather than invasive sampling with quantitative cultures to avoid unnecessary harm from invasive procedures. More invasive collection techniques such as bronchoscopy may be needed in immunocompromised patients or those who fail to improve with noninvasive testing and therapy. Nasal PCR screening for MRSA can have a high negative predictive value depending on the baseline rate of MRSA and can help deescalate therapy in these situations. Blood cultures are recommended in patients with HAP/VAP, and urine *Legionella* antigen testing and *Legionella* culture should be performed in patients for whom a hospital-acquired *Legionella* infection is a possibility. During community outbreaks, hospital-acquired influenza and SARS-CoV-2 transmission should also be considered.

Case check 32.5

VAP is thought to occur in up to 20% of patients who are mechanically ventilated for more than 48 hours. This patient's underlying chronic lung disease places him at increased risk for this entity as well. The increased endotracheal secretions, fever, and new infiltrate on chest imaging all suggest development of VAP in this patient, who has been mechanically ventilated. Empiric antimicrobial therapy should be started, and a culture of his endotracheal secretions is indicated to hopefully allow future directed tailoring of his treatment regimen. As this is a hospital-acquired infection, the patient is at increased risk for MDR organisms; therefore the facility's antibiogram should be considered when formulating his empiric therapy.

Treatment

Early implementation of appropriate therapy has been shown to decrease mortality in those with HAP/VAP. Broad-spectrum antimicrobial therapy should be started empirically and then modified based on culture data and clinical response. Empiric therapy should include coverage for *S. aureus*, *P. aeruginosa*, and other gram-negative bacilli at a minimum. Coverage for MRSA with vancomycin or linezolid is recommended if the local incidence of MRSA is high (>10% to 20% of *S. aureus* isolates) or unknown, there are risk factors present for MRSA including recent IV antimicrobial use, or there is a high risk of mortality.

Dual empiric antipseudomonal coverage with agents from different classes is recommended when local gram-negative resistance to a single agent is greater than 10% and for patients with structural lung disease, recent IV antimicrobial use, or high risk of death. Once susceptibilities are known, a single antipseudomonal agent can be used. Therapeutic options include extended-spectrum β -lactams, carbapenems, and antipseudomonal fluoroquinolones; aminoglycosides and colistin should be avoided unless no other options exist. For patients in whom *Legionella* infection is suspected, a macrolide antibiotic should be added unless a fluoroquinolone is already being used. A 7-day course of therapy is generally sufficient for HAP and VAP.

There has been significant focus on measures to prevent HAP, especially VAP. VAP intervention bundles, in particular, have been implemented in many hospitals to reduce the rate of VAP. These bundles include measures such as elevating the head of the bed to prevent aspiration, weaning sedation daily to decrease time on the ventilator and prevent complete suppression of the protective cough reflex, and providing oral care to decrease oral colonization with potential pathogens. Although these interventions have been shown to decrease the number of reported VAPs, many have not been shown to improve overall patient outcomes, including mortality.

Empyema

Case study

A 50-year-old male patient was hospitalized with 1 week history of respiratory symptoms and was diagnosed with CAP. Despite treatment with antimicrobials he continued to have low-grade fevers. A chest x-ray showed a left-sided pleural effusion. A CT scan of the chest revealed that the effusion was loculated (not free flowing, but trapped in multiple subcompartments as a result of a fibrous reaction to the infection).

Epidemiology

Empyema is a collection of purulent fluid in the pleural cavity, between the lung and the pleura. Most empyemas occur in association with a concurrent acute CAP, although they can occur with healthcare-associated processes as well. The accumulation of pleural fluid in the setting of pneumonia (PPE) is fairly common; up to 40% of hospitalized pneumonia patients will develop a PPE. However, most such accumulations are sterile, and only a small percentage (5% to 10%) will progress to an empyema.

Risk factors for empyema development include advanced or very young age, male sex, debilitation, comorbid disease(s) including alcohol abuse and IV drug use, and longer duration of symptoms before receiving appropriate therapy. Increases in the incidence of empyema in children have been noted after seasonal and pandemic influenza epidemics. Rates of empyema in the United States seem to be increasing, despite an overall decrease in hospitalizations for pneumonia.

Causes

Because the majority of empyemas are associated with CAP, the pathogens are similar. The most commonly isolated bacteria from empyemas in children and a significant contributor in adults is *S. pneumoniae*. After the introduction of PCV7 and PCV13, rates of invasive pneumococcal disease caused by many of the covered subtypes decreased significantly in both children and adults. *S. pyogenes* and *S. aureus* are also frequently implicated in community infections. Infections associated with aspiration and poor oral hygiene often involve other streptococci and anaerobic bacteria. Empyema among hospitalized patients is increasingly caused by aerobic gram-negative bacilli in addition to *S. aureus*. Empyemas may harbor multiple bacterial species, particularly if they are multiloculated (divided into multiple pleural spaces), caused by aspiration, or from a GI or intraabdominal source.

M. tuberculosis is also an important cause of empyema worldwide.

Pathogenesis

Empyema is usually a consequence of extension of infection directly from the underlying lung to the pleural space. Most empyemas occur in patients with community-acquired infections for whom there has been a delay in treatment. In patients with chronic pneumonias, such as those caused by *M. tuberculosis*, empyema may occur as a result of rupture of an underlying cavity into the pleural space. Empyema may also complicate chest surgery or chest trauma, both of which provide a direct route of infection to the pleural space. Hematogenous seeding of the pleural space can also occur with bacteremia. Less commonly, empyema results from contamination of the pleural space as a result of extension of a pyogenic process from the mediastinum, the paraspinal area, or the abdomen to the pleural space such as after esophageal rupture.

In general, an untreated pneumonia results in increased capillary permeability by active inflammatory cells recruited to the lung because of infection, resulting in fluid accumulation in the pleural space and development of an uncomplicated PPE. If left untreated, fibrin adhesions may develop and bacteria can enter, the end stage of which may be fibrosis and lung entrapment.

Characteristics of the empyema fluid create an environment in which elimination of offending pathogens is compromised. Opsonins and complement activity, which are necessary for proper phagocytosis of bacteria by infiltrating granulocytes, are present in reduced concentrations in empyema fluid. In addition the usefulness of antimicrobials in treating empyema is limited by the minimal blood supply to the area, resulting in reduced drug delivery, and by the low pH of empyema fluid, which can reduce the activity of antimicrobial drugs.

Case check 32.6

The presence of persistent fever despite treatment with appropriate antibacterial therapy suggests a source control problem. Antimicrobial drugs alone are insufficient treatment for a purulent fluid collection, such as an empyema, because blood flow and antimicrobial delivery into such a collection is minimal, resulting in a suboptimal drug concentration at the site of infection; drainage is required. PPEs, such as seen on this patient's chest imaging, should be sampled via thoracentesis, and if the results are consistent with an empyema, drainage with a chest tube or surgical means should be performed. Empyema is more likely with a protracted duration of symptoms before seeking medical care and starting appropriate antimicrobial therapy.

Clinical manifestations

The clinical presentation of a patient with empyema is often indistinguishable from the disease of the underlying lung. Patients can have chest pain on the affected side, fever, chills, and night sweats. Sepsis may develop. If the empyema is large, it might be detected during the physical examination as an area of absent or reduced breath sounds. If empyema is

not suspected based on the physical findings, it can often be detected as an abnormality on the chest x-ray. Pleural ultrasonography, often performed at the bedside, can help determine the feasibility of pleural fluid sampling and facilitate the procedure. A contrasted CT scan of the chest might be necessary to differentiate empyema from a lung abscess or lung consolidation and can help elucidate the etiology of the effusion.

Complications

The main consequence of empyema is persistence of infection. If the empyema is not drained and treated with appropriate antimicrobial agents, the infection causing the empyema might be difficult to eliminate. Persistent, poorly controlled infection can lead to the multiple complications associated with unresolved sepsis. A long-term complication of empyema is encasement of the lung in a thick capsule, which can reduce lung function. This can necessitate removal of the thickened pleural lining (pleural decortication), which may or may not restore the function of the underlying lung, depending on the duration of the dysfunction. Up to 30% of patients with empyema require surgical intervention, and mortality can be up to 15%. Advanced age and major comorbidities are risk factors for death.

Laboratory diagnosis

The distinction between a sterile PPE and empyema depends on the presence of a bacterial pathogen and inflammatory response and is made using pleural fluid cell counts, chemistry tests, and cultures. A thoracentesis (removal of pleural fluid through a needle or tube) is performed to obtain a sampling of the pleural space fluid. Pleural fluid specimens should be aspirated directly from the pleural space (and not from previously placed catheters or tubes) into an evacuated, sterile syringe. Any excess air in the syringe should be expelled promptly to increase the yield of anaerobic bacteria. A portion should also be inoculated into a blood culture bottle to increase the yield of bacteria.

Pleural fluid should be analyzed for cell count with differential, total protein, lactate dehydrogenase (LDH) concentration, and pH in addition to bacterial, fungal, and mycobacterial direct stained smears, and cultures. If malignancy is in the differential diagnosis, a fluid specimen should also be submitted for cytology. If the diagnosis of tuberculous pleural effusion is suspected, measurement of fluid adenosine deaminase may be helpful; a pleural biopsy sample for mycobacterial culture and *M. tuberculosis* PCR assay can increase diagnostic sensitivity. The sensitivity of pleural and blood cultures is variable and often low, especially in patients in whom there has been pretreatment with antimicrobial agents. In these cases, molecular diagnostic techniques may increase the identification of pathogens, such as multiplex PCR testing for common bacteria or 16S RNA PCR to identify pathogens.

Treatment

The mainstay of therapy for empyema is drainage of the infected fluid concurrent with appropriate antimicrobial therapy. Pleural fluid with purulence, a positive Gram-stained smear, or a positive culture requires drainage. A pleural fluid pH less than 7.20, loculated fluid, low fluid glucose, and

elevated fluid LDH level also suggest that the fluid is less likely to resolve with antimicrobial therapy alone and drainage is necessary. Drainage can be performed in many cases with insertion of a chest tube at the bedside or a pigtail catheter with radiologic guidance, potentially with the addition of lytic therapy. For more complicated cases in which these procedures do not drain the fluid, control the infection, and reexpand the lung adequately, video-assisted thoracoscopic surgery or thoracotomy with decortication might be needed. When a specific pathogen is identified from pleural fluid, blood, or respiratory cultures, antimicrobial therapy should be appropriately directed; in the absence of positive cultures, empiric therapy should be continued to cover the most common causes. The duration of therapy depends on the pathogen, adequacy of drainage, and clinical response.

Prevention strategies include appropriate early therapy for pneumonia to decrease the likelihood of empyema development. Vaccination of children and adults against *S. pneumoniae* has been successful in decreasing invasive pneumococcal disease, including empyema, related to the included vaccine serotypes.

Aspiration pneumonia

Case study

A 63-year-old male patient, who was a nursing home resident, was admitted to the hospital for treatment of recurrent urinary tract infections. He had several episodes of vomiting while he was in the nursing home. At the time of admission, he was somnolent, and pulse oximetry revealed hypoxia. A chest x-ray performed by the bedside showed a new infiltrate in the right lung posterior upper lobe. He was transferred to the intensive care unit for management of ARDS.

Epidemiology

Aspiration occurs when gastric or oropharyngeal contents are inhaled into the larynx or lower respiratory tract. Several syndromes can result, including aspiration pneumonitis, a noninfectious chemical injury; and **aspiration pneumonia**, a lower respiratory tract infection caused by inhalation of bacteria colonizing oropharyngeal or, in some cases, gastric secretions. These two syndromes are often difficult to differentiate clinically. In addition, CAP and VAP also likely result from microaspiration of bacteria colonizing the oropharynx.

The aspiration pneumonia discussed in this section will focus on those pneumonias thought to be caused by macroaspiration events. Aspiration pneumonia occurs in children and adults and is more common in hospitalized patients, those with dysphagia, or those who have a reduced level of alertness for a variety of reasons, including alcohol or sedative use. Other risk factors include poor oral hygiene and periodontal disease, esophageal dysmotility disorders, enteral feeding, ineffective cough reflex, and use of gastric acid-blocking medications.

Causes

Traditionally, aspiration pneumonia was thought to be predominantly caused by anaerobic pathogens, but more recent studies have isolated fewer anaerobes. Patients with community-acquired aspiration pneumonia were more likely to have

infections with *S. pneumoniae*, *H. influenzae*, staphylococci, and Enterobacterales, whereas gram-negative pathogens, including *P. aeruginosa*, were isolated more commonly from patients with hospital-acquired aspiration pneumonia. Anaerobic pathogens were isolated infrequently in these newer studies, but they may play a more significant role in patients with prolonged illness and development of complications, including lung abscesses, necrotizing pneumonia, and empyema. The most commonly identified anaerobes include *Bacteroides* spp., *Prevotella*, peptostreptococci, and *Fusobacterium* species.

Pathogenesis

Aspiration pneumonia follows the abnormal entry of upper airway or GI secretions colonized with bacteria into the lower respiratory tract. The likelihood of developing infectious pneumonia after aspiration depends on the frequency of aspiration, quality and quantity of material aspirated, and host defenses. Patients who are immunosuppressed by underlying disease and/or chemotherapy and patients with altered lung defenses (e.g., cigarette smoking, chronic lung disease, advanced age) are at increased risk for development of infection after aspiration of a bacterial inoculum. In addition, inhaled particulate matter can obstruct the airway, causing reduced clearance of bacteria and secretions, thereby predisposing to infection.

Chemical aspiration pneumonitis is thought to occur when inhaled gastric acid causes injury resulting in a severe inflammatory response and increased permeability of the tissue, potentially leading to edema, decreased lung compliance, and hypoxemia. Most of these cases are thought to be sterile, but later secondary bacterial superinfection can occur.

Case check 32.7

Microaspiration events occur even in healthy individuals but are much more common in patients with altered levels of consciousness and difficulty swallowing. Macroaspiration can occur in the setting of vomiting such as in this case. The acidic gastric contents can cause a chemical pneumonitis that can manifest itself with a relatively quick onset of hypoxemia and respiratory failure with fever and a new infiltrate on chest x-ray. This can be very difficult to differentiate from aspiration pneumonia in which there is an infection of the lung tissue after an aspiration event. This patient's residence in a nursing home places him at increased risk of colonization with MDR organisms in his oropharynx that can then be aspirated and cause infection.

Clinical manifestations

Symptoms of aspiration may be evident as coughing while the patient is eating food or drinking liquids or after an episode of emesis, although in many patients, these aspiration events are inapparent or "silent;" in other cases, the aspiration event is unwitnessed. It is often impossible to distinguish aspiration pneumonitis and aspiration pneumonia on clinical presentation alone because there is significant variability and overlap in clinical manifestations. Aspiration pneumonitis classically presents with a witnessed aspiration event and sudden increased coughing, wheezing, hypoxia, and possible progression to respiratory failure. These patients may have fever and significant infiltrates on chest radiography, despite having no active infectious process.

Aspiration pneumonia may present in a similar fashion with acute onset of fever, cough, and shortness of breath, or it may be more subtle. On chest x-ray, disease resulting from aspiration is more likely to involve parts of the lung that are dependent at the time of aspiration, usually the superior segments of the lower lobes and posterior segments of the upper lobes when the patient is supine. The lower lobes are more likely involved when the patient is upright, and right-sided lung involvement is twice as common because the right mainstem bronchus has a more direct course into the lower lobe of the lung.

Complications

Patients diagnosed with aspiration pneumonia carry a higher risk of morbidity and mortality compared with those diagnosed with non-aspiration CAP, even in the absence of other complications. If treatment fails, aspiration pneumonia can progress to a necrotizing pneumonia and lung abscess. Patients with lung abscess usually have a longer history of illness (weeks) and a more subtle onset of symptoms than patients with common acute bacterial pneumonia. Patients with lung abscess are also more likely to have putrid sputum and to complain of halitosis resulting from involvement of anaerobic bacteria in the lung infection. As with other types of pneumonia, empyema can also develop. Acute aspiration pneumonitis can rapidly lead to increasing hypoxia and ARDS.

Diagnosis

Obtaining specimens for the diagnosis of aspiration pneumonia is similar to methods described for CAP and HAP. The difficulty lies in distinguishing aspiration pneumonitis, a noninfectious process that does not benefit from antimicrobial administration, from aspiration pneumonia, which does warrant therapy. Several biomarkers have been studied in respiratory samples and serum to try to distinguish these two entities, but currently no reliable method exists.

Treatment

Treatment for acute aspiration involves airway clearance, oxygen and respiratory support, and treatment of bronchospasm and airway edema as needed. Empiric therapy for community acquired aspiration pneumonia should cover similar pathogens as in other CAPs; empiric therapy in a hospitalized patient should include broad-spectrum antimicrobials that provide coverage for aerobic gram-negative organisms. Anaerobic coverage should be included if risk factors are present (e.g., significant periodontal disease, necrotizing infection, lung abscess). Therapy should later be tailored to cover specific pathogens identified during culture. The duration of therapy is generally 5 to 7 days unless the infection is complicated (e.g. empyema, abscess). Evaluation by a speech therapist may be indicated to assess any impairment of swallowing mechanisms and silent aspiration. Preventive measures include good oral hygiene and positional feeding, although results of studies have been mixed.

Tuberculosis and other chronic infections

Bacterial pneumonias usually resolve completely over a period of weeks. On occasion, however, resolution of pneumonia is delayed, with radiographic lung abnormalities that persist beyond the alleviation of clinical symptoms. Some bacteria that typically cause acute pneumonias induce

necrotizing processes in the lung that can be slow to resolve, such as anaerobic lung infections, gram-negative bacillary pneumonias, and pneumonias caused by *S. aureus*. Some pneumonias are inherently slow in progression and chronic in nature; the most common of these are mycobacterial and fungal infections of the lung.

Case study

A 60-year-old male patient entered the emergency department complaining of cough and fever lasting several weeks. He reported night sweats and weight loss over the past few months. He admitted to heavily drinking alcohol on weekends and to staying in a homeless shelter most of the previous winter. The patient had a fever and was very thin. He coughed frequently during the examination. His chest x-ray revealed a right lung upper lobe infiltrate, with a small area of cavitation.

Epidemiology and causes

Mycobacteria are the most common pathogens causing chronic lower respiratory tract infections in immunocompetent hosts. Tuberculosis (TB), a disease caused by infection with *M. tuberculosis*, was responsible for approximately 10 million new cases in 2020 and 1.5 million deaths annually. In the United States, 7,860 cases of TB were reported in 2021, but up to 13 million people in the United States have latent TB infection. Most TB cases in the United States are diagnosed in foreign-born persons. The remainder of cases tend to occur among socially disadvantaged, older adult or very young, and immunocompromised patients. Substance abuse is an important behavioral risk factor in the United States. Infection with HIV is the most significant risk factor for TB infection reactivation or progression of primary TB infection globally, including in children. Infections with nontuberculous mycobacteria (NTM; e.g., *Mycobacterium avium* complex, *Mycobacterium kansasii*, *Mycobacterium abscessus*) can present with cavitary lung disease that is indistinguishable from TB but usually presents as nodular or patchy lung infiltrates superimposed on underlying lung disease (e.g., bronchiectasis, emphysema, pulmonary fibrosis, cystic fibrosis).

Opportunistic fungal pathogens, such as *Aspergillus* and *Cryptococcus*, can cause acute and chronic lower respiratory tract infections in immunosuppressed patients, and in the case of *Aspergillus*, in those with chronic underlying lung disease, but they rarely do so in immunocompetent hosts. In contrast, the fungal pathogens *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* can cause acute and chronic lower respiratory tract infections in immunocompetent hosts; only the chronic forms will be considered in this section. *Histoplasma* is endemic to the Mississippi and Ohio River valleys and a few Mideastern states, whereas *Blastomyces* is usually seen in regions adjacent to the Great Lakes and along the Ohio, Mississippi, and St. Lawrence riverways. *Coccidioidomycosis* exposure occurs in the southwestern United States.

Pathogenesis

Most of these organisms are acquired via inhalation. For *M. tuberculosis*, the organism becomes airborne when an infected person coughs, sneezes, or speaks. Fungal and NTM organisms

are acquired from environmental reservoirs. Chronic infections caused by mycobacterial or fungal pathogens typically elicit a granulomatous response in the lung that is distinct from the acute inflammatory response seen with acute bacterial pneumonias. Both humoral (specific antibody) and cellular (delayed-type hypersensitivity) responses are elicited by these pathogens. The cellular immune response to chronic lung infections is involved in both protective and tissue-destructive aspects of these illnesses.

Clinical manifestations

Chronic histoplasmosis and blastomycosis infections are often clinically indistinguishable from pulmonary TB, presenting with protracted productive cough, fevers, night sweats, weight loss, and malaise. Blastomycosis also can present characteristically as a pulmonary mass lesion, mimicking lung cancer with a nonproductive cough and few additional symptoms. Histoplasmosis can cause hilar and mediastinal lymphadenopathy, in some cases with compressive symptoms of other mediastinal structures secondary to lymph node enlargement. TB in children may be particularly difficult to recognize as the clinical presentation may be nonspecific in comparison with acute bacterial pneumonia; involvement of the peripheral lymph nodes is not uncommon and, when present, may provide a clue.

Case check 32.8

The symptoms seen in the setting of acute pneumonia (e.g., fever, chills, productive cough) can also be observed in patients with chronic pneumonias, but these and other symptoms may be less intense and less dramatic in onset. This can result in a greater delay between symptom onset and diagnosis. Because of the prolonged period of illness associated with chronic pneumonias, the patient can also exhibit signs that are not seen with acute infections, such as weight loss and slowly increasing debility. In patients with cavitary lung lesions, hemoptysis can occur. This manifestation was illustrated in the case presented at the beginning of this section. Upper lobe cavitary lung disease is suggestive of TB or other mycobacterial disease. However, because many infections that cause chronic pneumonia present with similar radiographic abnormalities, further studies must be performed for a specific diagnosis.

Mycobacterial and fungal infections are more likely to be severe and disseminated in immunocompromised patients, compared with immunocompetent hosts, potentially causing life-threatening complications. For example, *Aspergillus* spp. can cause overwhelming pneumonia in neutropenic patients, and cryptococcal pneumonia can cause fatal dissemination to the CNS in patients who are immunosuppressed after receiving chemotherapy or as a result of advanced HIV infection. Physical examination of patients with chronic pneumonia may reveal few abnormalities other than those associated with general debilitation. If dissemination is present, many of the discussed fungal infections may also involve the skin, which can provide clues to the cause and another area for tissue sampling and diagnosis. In addition to the history, chest radiography and CT of the chest are the most important initial diagnostic studies in establishing a presumptive diagnosis of chronic pneumonia.

Complications

The complications of chronic infectious pneumonias depend on the extent of the local and systemic spread of the infection, duration of the illness, and immunologic status of the host. Patients who develop extensive lung involvement with a chronic infection as a result of late, inappropriate, or failed medical intervention can eventually experience progressive debility and respiratory insufficiency. Infection dissemination beyond the lung in immunocompromised patients can result in infection of other vital organs and tissues, such as the CNS with cryptococcus, the endemic mycoses, and *M. tuberculosis* and the bone marrow, spleen, liver, and GI tract with histoplasmosis. Blastomycosis can spread to the skin, bones, and genitourinary tract, even in immunocompetent individuals, and causes ARDS in a subset of patients. Extrapulmonary spread generally increases the morbidity and mortality of these infections.

Laboratory diagnosis

Mycobacterial culture remains the gold standard for diagnosis of TB. Both automated systems with liquid media as well as solid media cultures are recommended to be performed. Liquid media cultures often yield growth faster, but they may be subject to contamination, and some isolates only grow on solid media; using both methods together provides the highest sensitivity. Once growth is seen, molecular diagnostic probes can be used for rapid mycobacterial species identification in many instances; matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry can also be used. Phenotypic drug sensitivity testing for first-line drugs should be performed on all isolates.

Smears of concentrated sputum samples prepared for mycobacterial culture should also be stained with acid-fast stains, such as Kinyoun or Ziehl-Neelsen stain or with a rapid fluorochrome stain to detect acid-fast bacilli (AFB) (Fig. 32.11). It is strongly recommended to test three separate 5- to 10-mL sputum samples to increase the sensitivity of detection; if sputum cannot be obtained including with induction techniques, flexible bronchoscopic sampling is recommended.

To complement the AFB stain of sputum specimens for rapid diagnosis, NAATs are approved for *M. tuberculosis* lung infections. NAATs use PCR assays and other methods to amplify and detect *M. tuberculosis* DNA and RNA in sputum, thus providing highly sensitive and specific methods to detect *M. tuberculosis* days to weeks before culture positivity.

Fig. 32.11 Acid-fast stain of sputum containing mycobacteria (red-stained organisms; arrow).

The sensitivity of these tests is greater for AFB smear-positive sputum than for smear-negative sputum. NAATs are recommended for all sputum specimens that exhibit AFB on direct sputum smears and for AFB smear-negative sputum when the clinical suspicion of TB is high. Molecular assays have been developed that, in addition to detecting the presence of *M. tuberculosis* in sputum specimens, can rapidly detect the presence of rifampin resistance (and in some cases resistance to other drugs), which can be critical to treating drug-resistant TB cases appropriately and expediently; genetic drug susceptibility testing is recommended in those who have risk factors for rifampin resistance.

Unfortunately, because of the paucibacillary nature of TB in children, each of the aforementioned diagnostics has a decreased sensitivity in this population, so TB is often a clinical diagnosis. Obtaining good-quality specimens in young children can also be a challenge. First-morning gastric aspirates can be used to collect swallowed sputum for TB testing when other forms of respiratory specimen collection is limiting. Extrapulmonary TB can be diagnosed using similar techniques as for pulmonary specimens, although the yield is often less. There is less experience with the use of NAATs for TB diagnosis at extrapulmonary infection sites; however, current guidelines recommend its use. Cell counts, chemistries, and adenosine deaminase can be determined on pleural, pericardial, peritoneal, and cerebrospinal (CSF) fluids. Histologic examination may also be helpful for extrapulmonary tissue samples to identify necrotizing granulomas and the presence of AFB organisms on special stains.

Detection of latent TB infection (LTBI), asymptomatic infection without active disease, identifies patients who can be evaluated for treatment to prevent progression to active disease. This may avert both morbidity and mortality in the index patient as well as eliminate the opportunity for transmission to others if effective. Persons who are at low risk for *M. tuberculosis* infection and low risk for development of active disease if infected should not be tested for LTBI. Two tests currently exist to diagnose prior TB exposure: a tuberculin skin test (TST) using purified protein derivative (PPD) and interferon gamma release assays (IGRAs). A positive test result must be followed by an assessment for signs or symptoms of active TB, including imaging of the chest. Patients with clinical symptoms or suspicious findings by chest radiography require assessment with sputum samples to ensure that no active disease is present. Although both PPD and IGRAs are approved for use in detecting LTBI, neither is sufficiently sensitive to rule out the diagnosis of active TB based on a negative test as false-negative results are not uncommon in active disease.

Because NTM can colonize the respiratory tract in the absence of invasive lung disease, more than one positive sputum specimen for the same species in the context of a progressive clinical and radiographic pulmonary process in the absence of another pathogen is generally needed to establish an association between the NTM infection and the illness. Therefore isolation of an organism (e.g., *M. avium* complex) from a single sputum specimen is generally insufficient to establish a causative diagnosis or warrant institution of therapy.

For fungal infections, isolation in culture is the gold standard. Brain heart infusion agar with 10% sheep blood is used for isolation of the more fastidious dimorphic fungi (e.g., *B. dermatidis*, *C. immitis*, and *H. capsulatum*). Sabouraud's dextrose agar is often used for less fastidious fungi like

Cryptococcus spp. Chronic pulmonary histoplasmosis has a higher yield from respiratory culture than acute disease. Fungal cultures of the blood and bone marrow may be relatively high yield in disseminated histoplasmosis. Respiratory cultures (sputum or bronchoscopy) are often able to isolate *Blastomyces*. *Coccidioides* species may be difficult to culture as most patients have a nonproductive cough. Tissue specimens obtained by transbronchial biopsy at bronchoscopy or lung biopsy are ideal to demonstrate the invasiveness of *Aspergillus* because a positive respiratory culture alone may simply represent airway colonization; a presumptive diagnosis is often made clinically. Direct microscopic examination of respiratory secretions should also include preparations to detect fungal agents; potassium hydroxide and calcofluor white are commonly used to detect yeast cells and hyphal elements.

In tissue specimens, additional stains, such as Gomori methenamine silver (GMS) (Fig. 32.12) or periodic acid–Schiff (PAS), may provide a presumptive diagnosis. *B. dermatitidis* is identifiable as a thick-walled large yeast with characteristic, single, broad-based budding. *H. capsulatum* is a smaller yeast with narrow-based budding. Depending on the severity of the clinical illness, empiric therapy is often started based on a presumptive diagnosis from the clinical presentation and results of histopathology studies and special stains while awaiting culture confirmation from the microbiology laboratory because, like TB, many of these cultures grow very slowly, and isolation may take weeks.

Fungal antigen and antibody testing can be a useful adjunct to microscopic studies for the diagnosis of fungal infections pending culture confirmation. Urinary antigen assays for *H. capsulatum* and *B. dermatitidis* have sensitivities greater than 90% in certain populations and presentations of disease; antigen testing can also be used in cerebrospinal and bronchoalveolar lavage fluids. Serum antigen testing for *H. capsulatum* may help increase sensitivity when the clinical suspicion is high. In both of these endemic mycoses, serial monitoring of urine antigen levels can be used to monitor response to therapy and

assess for relapse. A serum antigen assay can detect *C. neoformans*. Serum and bronchoalveolar lavage galactomannan assays may aid in the noninvasive diagnosis of *Aspergillus* infections. Cross-reactivity with other fungal pathogens exists with many of the antigen tests. Serologic tests are used to aid in the diagnosis of coccidioidomycosis and some presentations of histoplasmosis. NAATs are not standardized or widely available but hold promise for the future.

Culture studies in patients with chronic pneumonias require close communication between the clinician and clinical microbiologist. It is necessary to use special techniques to process respiratory secretions and lung tissue specimens for the identification of mycobacterial and fungal pathogens. Furthermore, in some cases (e.g., TB, coccidioidomycosis), isolation of the pathogen creates a potential biohazard in the diagnostic laboratory if the appropriate precautions are not employed. Because of the public health implications of the potential transmissibility of laryngeal or pulmonary TB, any positive respiratory mycobacterial smear or culture should be reported to the primary care provider and local public health departments, and proper airborne isolation precautions should be instituted in health care facilities until the organism is speciated to discriminate between TB and NTM infection, the latter of which is not communicable from person to person and does not require isolation.

Treatment

The presence of *M. tuberculosis* in expectorated sputum is diagnostic and must be treated. Therapies vary in duration, drugs prescribed, and dose and frequency. Regimens for active disease and LTBI also vary. Patients with pansusceptible TB receive a four-drug regimen of rifampin, isoniazid (also known as *isonicotinic acid hydrazide* [INH]), pyrazinamide, and ethambutol (RIPE TB regimen) for an initial 2-month induction period. Once the isolate has been confirmed to be susceptible to INH and rifampin, pyrazinamide and ethambutol therapy can be discontinued. The initial 2-month intensive phase is

Fig. 32.12 Lung exudate from a patient with a hematologic disorder showing alveoli containing branching fungal elements. **A**, Hematoxylin and eosin stain. Arrows indicate fungal elements. **B**, Gomori methenamine silver stain. (Courtesy Dr. Shirlyn B. McKenzie.)

followed by therapy with INH and rifampin for an additional 4-month or 7-month continuation phase. Patients with cavitary disease and persistent *M. tuberculosis* isolation in culture require longer courses because of a higher risk of relapse.

Ideally, therapy is delivered using what is termed *directly observed therapy* (DOT) because of problems associated with failure of patients to adhere to the prolonged treatment. Poor patient compliance can result in treatment failure and emergence of TB drug resistance because of inadequate therapy and resulting bacterial selection. In addition, DOT facilitates close monitoring for drug side effects including hepatotoxicity. Treatment duration must be prolonged (15–24 months) for MDR TB, which is defined as resistance of the *M. tuberculosis* isolate to at least INH and rifampin. In these cases, therapy should always be based on antimicrobial susceptibility testing results and initiated after consultation with a specialist in TB therapy. Extrapulmonary TB that involves the CNS and bone also warrants a longer course of therapy. Treatment of LTBI is critical to preventing progression to active disease, especially in high-risk groups, such as those with HIV infection. This generally involves the use of rifampin alone for 4 months, rifapentine with INH for 3 months, or 3 months of rifampin with INH. In patients with active TB, treatment of comorbid HIV infection is paramount.

Therapy for NTM varies based on the specific mycobacteria isolated as well as the clinical condition of the patient, and single positive NTM cultures are usually an inadequate basis for initiation of therapy; repeated culture confirmation is useful. Multiple agent regimens for a prolonged period are often necessary. Cure of the infection is not always a realistic goal, and treatment in many cases is directed at control of symptoms. In a subset of cases, the toxicity of therapy may outweigh the expected benefits, and close observation may be the most appropriate approach.

Chronic pneumonia and disseminated disease caused by fungal infection also require prolonged therapy. In cases of severe illness, therapy can be initiated with an IV lipid amphotericin B preparation and then followed with an oral azole agent for prolonged treatment (minimum of 12 months); oral therapy can be used as initial treatment for patients with mild-to-moderate illness. The oral antifungal agents of choice depend on the fungal pathogen being treated. For example, itraconazole is often useful for the treatment of infections with *H. capsulatum* and *B. dermatitidis*, but voriconazole is the oral agent of choice for invasive *Aspergillus* infection. Fluconazole has excellent activity against *Coccidioides*. For many of the azoles, therapeutic drug monitoring is critical to ensure absorption and appropriate drug levels for treatment.

Respiratory tract infections in the immunocompromised host

Opportunistic pathogens generally do not cause significant disease in hosts with normal immune system function but rather require an impairment of host defense mechanisms to cause disease; patients who are susceptible to such opportunistic infections are referred to as *immunocompromised hosts*. The expanded use of chemotherapeutic regimens for malignancy, increasing use of solid organ and hematopoietic cell

transplantation, prolonged survival of patients with congenital immune deficiencies and autoimmune disorders, and the HIV/AIDS epidemic have all contributed to increasing numbers of immunocompromised hosts. Pulmonary infection is the most common form of documented infection in these individuals. Because early diagnosis and prompt, directed therapy are the cornerstones of successful treatment of infections in immunocompromised patients, the clinical microbiology laboratory plays an important role in their management.

Patients with human immunodeficiency virus

Case study

An 18-year-old male patient with no significant medical history presented to the emergency department with a history of cough and shortness of breath with exertion, along with subjective fevers, chills, and fatigue. He was noted to be hypoxic. A chest x-ray showed bilateral infiltrates in a diffuse butterfly pattern involving both central lung fields. The patient reported a history of IV drug use, with frequent sharing of needles.

The occurrence of infections in patients with HIV is a combined function of the extent of underlying host immunodeficiency and pathogen virulence. The CD4 cell count remains the best surrogate marker for assessing the status of the host immune system and associated risk of infectious complications. With higher CD4 cell counts, it is more likely that infections will be caused by more virulent organisms, such as *S. pneumoniae* or *M. tuberculosis*, that are also capable of causing disease in immunocompetent hosts. As the CD4 cell count decreases, the risk increases for infection with environmentally ubiquitous opportunistic pathogens that rarely cause disease in normal hosts, including *Pneumocystis jiroveci*, and dissemination of infections that would otherwise be contained locally in a healthy individual (Table 32.4).

Epidemiology

With the availability of highly active antiretroviral therapy (HAART) as well as preventive antimicrobial therapy, the incidence of most infections in patients with HIV has significantly decreased in high-income countries. Nevertheless, respiratory infections remain a common occurrence, especially in patients with very low CD4 cell counts who are not receiving effective antiretroviral therapy (ART). *P. jiroveci*, causing *Pneumocystis pneumonia* (PCP), remains the most common AIDS-associated opportunistic infection, with most cases occurring when the CD4 cell count is below 200/mm³. Initial *Pneumocystis* infection occurs in early childhood, and disease in HIV-infected individuals constitutes both reactivation of latent infection as well as new infections from airborne spread. Other fungal pulmonary infections in this population include infections with the endemic fungi *H. capsulatum* and *C. immitis/Coccidioides posadasii*, both of which cause disseminated disease with increased incidence in patients with advanced HIV infection. *C. neoformans* is an encapsulated fungus that is widespread in the environment and usually causes meningitis, meningoencephalitis, or disseminated disease in AIDS patients with CD4 cell counts less than 100/mm³, but

Table 32.4 Respiratory pathogens associated with absolute CD4 cell count in patients with HIV infection

Pathogen	CD4 cell count (/mm ³)
Bacteria	
<i>Mycobacterium tuberculosis</i>	Any
<i>Mycobacterium avium</i> complex	<50
<i>Streptococcus pneumoniae</i>	Any
<i>Haemophilus influenzae</i>	Any
Protozoa	
<i>Toxoplasma gondii</i>	<100
Fungi	
<i>Pneumocystis jiroveci</i>	<200
<i>Coccidioides immitis</i>	<250
<i>Histoplasma capsulatum</i>	<150
<i>Cryptococcus neoformans/gattii</i>	<100
Viruses	
Influenza virus	Any
Cytomegalovirus	<50
<i>HIV</i> , Human immunodeficiency virus.	

localized pulmonary disease also occurs. *Cryptococcus gattii* is less common and, in the United States, has been identified primarily on the West Coast. Invasive *Aspergillus* fungal infections are rare and often associated with other risk factors, including neutropenia and corticosteroid use.

Patients with HIV infection with preserved CD4 cell counts still have an increased risk of several respiratory infections compared with individuals not infected with HIV. Bacterial pneumonia is common, occurring with increasing frequency at all CD4 cell counts. The same pathogens causing the most diseases in immunocompetent hosts (*S. pneumoniae* and *H. influenzae*) are responsible in HIV-infected patients as well. *P. aeruginosa* and *S. aureus*, however, are seen with increasing frequency in this group in community-acquired infections. Influenza is a common cause of upper respiratory tract infections and bronchitis; cases of influenza pneumonia may be complicated by bacterial superinfection with *S. pneumoniae* and *S. aureus*.

TB is one of the most common HIV-related opportunistic infections worldwide and is a major cause of death, especially among those with advanced HIV disease. TB can occur at any CD4 cell count level, but those with advanced HIV infection are more likely to develop TB disease and disseminated infection. Because patients with HIV infection have a significantly increased risk of progression of recent TB infection to active disease and of reactivation of LTBI, the diagnosis of TB remains an important consideration, even in areas of the world with a low TB prevalence.

Clinical manifestations

PCP tends to have a subacute onset of progressive symptoms, including dyspnea, dry cough, and fever. Hypoxemia is characteristic of PCP and helps categorize the severity of the disease. In general, HIV-infected individuals with CD4 cell counts of at least 300/mm³ are more likely to have histoplasmosis limited to the respiratory tract, whereas disseminated histoplasmosis more commonly occurs in HIV-infected

Case check 32.9

In the Case Study at the beginning of this section, the patient has a history of IV drug use, which is a risk factor for HIV infection. As noted, the incidence of most infections in HIV-infected patients has significantly declined, although it remains a common occurrence in patients with very low CD4 cell counts. PCP remains the most common AIDS-associated opportunistic infection. Patients with PCP classically present with a subacute onset of progressive dyspnea, fever, and nonproductive cough. Hypoxemia, by pulse oximetry or arterial blood gas measurement, is a classic finding. Chest imaging usually reveals diffuse bilateral lung changes, although the radiographic presentation can vary widely. Samples for laboratory testing should be taken from such patients to identify and confirm the diagnosis of HIV infection and the cause of the respiratory disease.

patients with CD4 cell counts less than 150/mm³, and it can involve the lungs, skin, bone marrow and reticuloendothelial system, GI tract, and CNS. Symptoms may include fever, weight loss, cough, dyspnea, diarrhea, abdominal pain, and headache, depending on the areas affected. If the infection involves the bone marrow, cytopenias may be evident on laboratory blood tests. Coccidioidomycosis can have diverse presentations, ranging from focal or diffuse respiratory disease to meningitis and other systemic involvement. As with many other infections, disseminated disease is more common with advanced immunosuppression (CD4 cell count <250/mm³). Cryptococcal pulmonary infection manifests itself with cough and dyspnea, which is indistinguishable from other pulmonary infections; it can also manifest as ARDS in some cases.

As in immunocompetent individuals, bacterial pneumonias present with an acute onset of respiratory symptoms, such as fever, chest pain, and productive cough. The clinical manifestations of TB depend on the extent of disease. Disease limited to the lung may result in a chronic cough with fevers and night sweats similar to those in immunocompetent hosts, whereas disseminated disease can result in progression to sepsis.

Laboratory diagnosis

Because of the large differential diagnosis that often exists for HIV-infected patients with respiratory infections and the importance of timely directed therapy, establishing the diagnosis is crucial. For patients who are actively coughing or for whom sputum induction methods are fruitful, sputum samples can be used for many of these tests. If a specific diagnosis is not established, bronchoalveolar lavage can be used to identify HIV-related pathogens in samples from the lower respiratory tract.

P. jiroveci identification in respiratory secretions is usually done by direct immunofluorescent antibody (DFA) testing, staining with one of many methods to detect the cysts (Fig. 32.13), or PCR assay. Serum β -D-glucan testing, while nonspecific, can be useful as an adjunct or screen. Elevated serum LDH levels are also commonly seen but are also nonspecific.

Histoplasma antigen can be detected in the urine and serum of most patients with disseminated infection and diffuse acute pulmonary histoplasmosis. In addition, the *Histoplasma* antigen can be used to monitor response to treatment. *H. capsulatum* can also often be cultured from respiratory secretions, blood, and bone marrow, although cultures need to be held for at least 4 weeks. Pathology specimens should be stained and examined for characteristic yeast forms.

Fig. 32.13 Gomori methenamine silver stain of bronchoalveolar lavage with *Pneumocystis jirovecii* (black-stained cysts).

Coccidioidomycosis is often tested for using serum and CSF, although these tests less often give positive results in immunocompromised individuals. When positive, complement fixation serology can be used to follow response to therapy. Positive culture of clinical specimens, including respiratory secretions, or demonstration of characteristic spherules in tissue specimens can make a definitive diagnosis of coccidioidomycosis. This pathogen is of particular importance for the laboratory because if it is not handled with appropriate precautions, it can become aerosolized and inhaled by laboratory staff, resulting in acute infection. It is important that primary health care providers notify the laboratory when this agent is suspected. Urine and serum antigen tests for coccidioidomycosis are also available commercially.

The serum cryptococcal antigen is less likely to be positive in localized cryptococcal pneumonia compared with disseminated cryptococcosis. However, antigen detection is useful to confirm the diagnosis because the assay has excellent specificity; serial titers are not helpful in monitoring response to therapy. Positive blood cultures for *C. neoformans* are also more common when CNS infection is present. All patients with positive cryptococcal testing or suspected disease should undergo CSF testing to assess for CNS disease.

Gram stain and bacterial cultures of expectorated sputum may be helpful for patients suspected of having bacterial pneumonia. In addition, blood cultures should be obtained because *S. pneumoniae* bacteremia is seen more commonly in HIV-infected patients with pneumococcal pneumonia than in immunocompetent patients. Urinary antigens for *S. pneumoniae* and *L. pneumophila* may also be helpful. The diagnosis of TB is identical to the methods used in immunocompetent hosts. Evidence of prior exposure to TB (i.e., LTBI) can be assessed by TST or IGRA. If positive results are obtained or the patient has suggestive symptoms, active disease must be ruled out; TSTs and IGRAs are not sufficiently sensitive for this purpose. Assessing patients for active pulmonary disease involves obtaining sputum samples for AFB smear and culture and *M. tuberculosis* NAAT in patients whose AFB smear is positive or whose suspicion of disease is high.

Treatment

First-line therapy for PCP is trimethoprim-sulfamethoxazole with adjunctive steroids in patients with moderate to severe disease (as evidenced by the degree of hypoxemia) to counter

the innate immune response. Many patients with moderate to severe disease require mechanical ventilatory support during therapy, and mortality remains relatively high. Once treatment has been completed, antimicrobial prophylaxis (preferably with lower-dose trimethoprim-sulfamethoxazole) should be continued until persistent reconstitution of the immune system occurs, as demonstrated by an increasing CD4 cell count greater than 200/mm³ for at least 3 months.

Pulmonary cryptococcal and coccidioidomycosis infections can be treated with fluconazole in mild to moderate cases. For histoplasmosis, itraconazole is the therapy of choice. In severe disease with any of these fungal pathogens, lipid amphotericin B preparations are used in the initial phases of treatment, with transition to oral azole therapy in later stages once improvement is noted. The duration of therapy for these infections depends, in part, on whether the immune system is able to recover, similarly to PCP. However, in cases of diffuse pulmonary or disseminated coccidioidomycosis, life-long treatment is often recommended because of the high risk of relapse.

Treatment of active TB involves the same agents as for non-HIV-infected individuals, with the exception that drug-drug interactions between anti-TB medications and ART may necessitate slight modifications in TB or HIV regimens, dose adjustments, and close monitoring for toxicity. Because of the high risk of progression to active TB, HIV-infected patients with evidence of LTBI should be offered therapy to prevent progression to active disease.

HAART is the most important strategy for preventing opportunistic infections, especially because many of these pathogens are ubiquitous in the environment, and it is impossible to avoid exposure. One goal of HAART is to maintain the host immune response, evidenced by the CD4 cell count, at a level that reduces susceptibility to these opportunistic infections. Current data suggest that early initiation of HAART is beneficial in most cases and should be considered. Prophylaxis for opportunistic infections is often provided when the CD4 cell count decreases below certain levels. Other preventive measures for respiratory infections in patients with HIV infection include administration of pneumococcal and annual influenza vaccines.

Patients with other immunocompromised states

Case study

A 29-year-old male patient with a history of chronic myelogenous leukemia (CML) treated with hematopoietic cell transplantation presented to the oncology clinic with a 3-day history of worsening fatigue and cough with yellow-green sputum, but no fever. A chest CT scan showed pulmonary micronodules and focal consolidation, with necrosis and abscess formation within the areas of consolidation. The consolidation had worsened compared with a previous CT scan performed 1 month earlier. The patient had been taking immunosuppressive medications for hematopoietic cell transplantation.

Infections in immunocompromised patients depend on the interplay of several factors, such as the specific deficiencies in

immune system function, particular exposures of the patient, and, in the case of transplantation, the donor, and measures taken to mitigate infection risk, including antimicrobial prophylaxis. Neutrophils, or granulocytes, are an important component of the innate immune system. A decrease in absolute number below $500/\text{mm}^3$ (neutropenia), as seen with hematologic malignancies and after chemotherapy (including preparatory regimens before hematopoietic cell transplantation), or a defect in neutrophil function, as seen with some congenital disorders (e.g., chronic granulomatous disease), can result in increased susceptibility to infection. Impairments of the adaptive immune system include decreased B-cell function (humoral immunity) and decreased T-cell function (cell-mediated immunity). These are seen as a consequence of myelosuppressive and myeloablative chemotherapy, with immunosuppressive medications used post-hematopoietic cell and solid organ transplantation, and with certain congenital disorders. Exposures to infectious agents can occur in the community before hospitalization and transplantation and place the patient at risk for reactivation disease (e.g., *M. tuberculosis*, CMV), be transmitted in a donor organ at the time of transplantation (e.g., *Aspergillus* colonization in lung transplantation), or be acquired from the hospital setting (hospital-acquired infection).

Epidemiology

Patients with compromised immunity are at risk for all of the typical infections an immunocompetent person might acquire as well as opportunistic pathogens that are not clinically significant in the presence of an intact immune system. Neutropenia and defects in neutrophil function predispose patients to infections with bacteria, such as *S. aureus* and *P. aeruginosa*, and fungi, including *Aspergillus*, *Mucorales*, and *Candida*. These are most often seen in patients receiving chemotherapy and in patients in the immediate post-hematopoietic cell transplantation period; these patients often present with fever while neutropenic.

Case check 32.10

The patient with CML who has had hematopoietic stem cell transplantation is at risk not only for virulent infections that affect the immunocompetent population but also for development of opportunistic infections that require compromised host defenses to cause disease. His presentation with consolidating and necrotic micronodules that have slowly progressed over time is worrisome for an invasive fungal infection such as aspergillosis. Any conditioning regimen the patient received before transplantation (if recent), any recent neutropenia, and his chronic steroid use all put him at increased risk for invasive aspergillosis, which generally does not cause significant disease other than in patients who are immunocompromised or have chronic underlying lung disease. Given the delay in making a definitive diagnosis with a fungal culture and pathology and the patient's immunocompromised status, empiric antifungal therapy is warranted.

Defects in humoral immunity, such as hypogammaglobulinemia, result in recurrent respiratory infections in patients with congenital disorders, including an increased risk of infection with encapsulated organisms such as *S. pneumoniae* and *H. influenzae* and viral infections in patients recovering

from myeloablative therapy or receiving immunosuppressive medication.

Patients with acquired cell-mediated immunity defects, such as those seen with HIV infection or solid organ transplantation, take the longest time to recover, leaving them at risk for a myriad of infections, including mycobacterial infections such as TB; fungal infections including *P. jiroveci* and *H. capsulatum*; bacterial infections such as *Legionella* spp., *S. aureus*, and *Nocardia* spp.; and viral infections including CMV and other herpesviruses. Recovery of adaptive immunity can be significantly delayed in patients with chronic graft-versus-host disease (GVHD) and patients with graft rejection, both of whom generally require further immunosuppressive therapy in addition to the maintenance immunosuppression regimen they are already receiving.

Infections within the first month after transplantation are generally hospital acquired in origin with occasional donor-derived infections in this period. Immunosuppression is most intense within the first 12 months after transplantation, and opportunistic infections predominate during this time; prophylaxis can delay many of these infections, which may subsequently develop within a few months after stopping therapy. Later infections are more likely to be the same community-acquired infections that affect immunocompetent hosts.

Clinical manifestations

In general, immunocompromised hosts may not present with the same symptoms as immunocompetent individuals; manifestations of infections may be muted or atypical, necessitating a high index of suspicion. Infections with encapsulated organisms, such as pneumococcal pneumonia, are more common and may be more severe than in immunocompetent hosts. Given frequent exposure to broad-spectrum antimicrobials, long stays in the hospital, and other comorbidities, antimicrobial-resistant bacteria, including Enterobacterales, *Staphylococcus*, and *Pseudomonas*, are seen more commonly in hospital-associated cases. *Nocardia* spp. often cause disseminated infection in immunocompromised hosts, affecting the lung, brain, and skin.

Invasive *Aspergillus* infections usually involve the lower respiratory tract but can also affect the sinuses and skin. *Aspergillus* spp. can cause infection at the tracheal anastomosis after lung transplantation or pulmonary parenchymal disease in neutropenic leukemia patients. The risk of this infection is increased with neutropenia lasting longer than 2 weeks, corticosteroid use, GVHD, and fungal colonization of lung transplants. Pulmonary PCP in transplant patients can often have a more fulminant course with increased morbidity and mortality compared with that in HIV-infected patients. PCP has become increasingly less common with the use of routine prophylaxis after transplantation and with prolonged high-dose steroid use. In addition, many long-term chronic immunosuppressive regimens are now designed to be steroid sparing, further decreasing the risk.

Like aspergillosis, mucormycosis primarily affects the sinuses (rhinocerebral disease) and respiratory tract in susceptible individuals. Patients may present with signs and symptoms typical of pneumonia such as fever, cough with occasional hemoptysis, and dyspnea, but the course is often rapidly progressive. For cryptococcal pulmonary infection, the lung is the usual portal of entry for disseminated infection,

which frequently involves the CNS and causes fever, headache, and meningeal symptoms. As discussed earlier in the "Tuberculosis and Other Chronic Infections" section, the endemic mycoses may demonstrate an increased severity of disease in immunocompromised individuals.

Viral respiratory infections are common in all stages of the posttransplantation period. RSV, influenza virus, parainfluenza virus, adenovirus, and hMPV are commonly detected. CMV is among the most important causes of viral infection in transplant patients, and although some infections are asymptomatic, others can be severe. CMV syndrome manifests as fever in the presence of viremia. Symptoms of CMV tissue-invasive disease depend on the organ affected. Pneumonia can present as fever and dyspnea, whereas diarrhea and abdominal pain or vision loss may indicate involvement of the GI tract and retina, respectively.

As is the case with HIV-infected individuals, LTBI in the recipient can reactivate during the posttransplantation period; donor-derived infection or new infection caused by posttransplant exposure can also occur. Symptoms are dependent on the extent of disease. The possibility of LTBI should be assessed and treated when detected before transplantation, whenever possible.

The parasitic helminth *Strongyloides stercoralis* can cause life-threatening infection in immunocompromised hosts. The parasite is most prevalent in tropical and subtropical climates. In the United States, the southeastern states have the highest risk. Once acquired, *S. stercoralis* can remain dormant in the GI tract for decades. In patients receiving steroids and in transplant recipients, larvae can penetrate the bowel wall and invade surrounding tissues, causing a hemorrhagic enterocolitis and pneumonitis. Dissemination of the larvae is frequently accompanied by bloodstream invasion of gram-negative enteric bacteria and meningitis.

Patients who are profoundly neutropenic after chemotherapy commonly develop fevers during this period. Infection is documented in only about 20% to 30% of cases, although most patients receive empiric therapy, and infection may not be diagnosed in additional patients because of the limitations of diagnostic testing.

Laboratory diagnosis

The approach to the diagnosis of opportunistic respiratory tract infections in this patient population is similar to that used for patients with HIV and, in many cases, immunocompetent hosts. The same general principle also applies regarding the reduced ability to rely on parameters of host immune response (i.e., antibody production and inflammatory reactions) and the increased emphasis on histopathology and culture identification for diagnosis. Differentiating GVHD and graft rejection from infection is also critical. Because the differential diagnosis is so much larger for immunocompromised individuals, identifying a pathogen is even more critical, and the testing approach is often appropriately comprehensive.

Viremia, including for CMV, is generally assessed using quantitative serum PCR testing; tissue-invasive disease generally requires histologic evidence of the pathogen, however, as a positive PCR from the lung, for example, may represent viral shedding caused by acute illness, and a negative serum

PCR does not rule out tissue-invasive disease. In some cases, the diagnosis is empiric.

Treatment

Treatment of these infections is identical to that of similar infections in immunocompetent or HIV-infected patients in most cases, but a few differences warrant discussion. In general, immunocompromised patients may become worse much more quickly compared with immunocompetent hosts; therefore empiric therapy is generally warranted (e.g., for febrile neutropenia) while the diagnostic workup is in progress. Antimicrobial resistance may also be more of a concern in this patient population, both with bacterial and viral pathogens, and risk factors for drug resistance should be sought when considering an empiric regimen. It is also critically important to be aware of potential drug interactions because many antimicrobials can interact with immunosuppressive medications, placing patients at risk for increased toxicity or rejection of the graft, depending on the specific interaction. In patients receiving long-term immunosuppression for transplants, the occurrence of certain infections may indicate a state of overimmunosuppression, and when possible to accomplish without sacrificing graft survival, reduction in the intensity of immunosuppression is an important therapeutic tool.

Prophylactic antimicrobials to prevent PCP and other fungal infections and CMV and other herpesvirus infections are often used when chemotherapy is given or when transplantation is performed to reduce the incidence of these infections in the early posttransplantation period. Trimethoprim-sulfamethoxazole prophylaxis, which is commonly used to prevent PCP, is also effective for *Nocardia*, although some breakthrough infections do occur. For CMV, most transplantation centers use universal antiviral prophylaxis after transplantation or monitor patients with serial serum CMV antigen or PCR assays and preemptively begin treatment with the first signs of viremia. As is true for HIV-infected patients, vaccination also represents an important tool for infection prevention in these groups, including for *S. pneumoniae* infection and influenza.

Infection control measures become increasingly important when dealing with immunocompromised patients, who are at increased risk for complications and death. Because most respiratory pathogens in hematopoietic cell transplantation are acquired via inhalation, patients are often placed in what is termed a *protective environment room*, which has an increased number of air changes per hour, positive-pressure air flow, and high-efficiency particulate air (HEPA) filtration to remove some of these pathogens from inspired air. Adherence to handwashing and contact precautions will also help reduce the transmission of pathogens from health care workers and among patients.

Bioterrorism and respiratory infections

Since the anthrax attack in the United States in 2001, the threat of biological agents as weapons to cause mass death has become an important national security and public health issue. The CDC has labeled anthrax, plague, and tularemia as category A bacterial agents, which constitutes the highest

level of threat (see [Chapter 30](#)). All of these organisms can be aerosolized for delivery to the respiratory tract. The initial clinical presentation of these pulmonary illnesses is similar to that observed with common bacterial respiratory pathogens, but the subsequent course can be fulminant and rapidly fatal. Therefore the greatest diagnostic challenge is clinical suspicion of these rare pathogens in the differential diagnosis of pneumonia and the related use of appropriate diagnostic studies or resources. It is important for the clinician to discuss the possibility of these agents with the laboratory because infection can be transmitted to laboratory personnel with manipulation of the culture if it is not handled properly.

Inhalational anthrax caused by *Bacillus anthracis* has an incubation period of 1 to 7 days. Patients may initially present with fever, but subsequently develop rapidly progressive pneumonia and multisystem organ failure. Blood and sputum cultures are often positive for gram-positive bacilli that are nonhemolytic, nonmotile, and catalase positive. Such isolates are referred to reference laboratories in the Laboratory Response Network (LRN), where identification can be confirmed by molecular diagnostic testing, such as PCR assay. Anthrax lethal factor toxin in plasma and serology should also be pursued. Inhalational anthrax is not communicable from person to person.

Pneumonic plague is caused by *Yersinia pestis*. Plague is endemic in some areas of the western United States and other parts of the world where rodents serve as a reservoir. Pneumonic plague represents the least common form of endemic cases but should be expected in the event of bioterrorism-related aerosol release, in which the organism is inhaled. A short incubation period of hours to days precedes the sudden onset of fever and rapid respiratory failure. Pneumonic plague can be spread from person to person, and droplet precautions should be applied in suspected cases. Sputum, tissue, and blood cultures from infected individuals may show plump, gram-negative bacilli that can exhibit bipolar staining (closed safety pin–like appearance) with Giemsa or Wright stains; the organism grows well in culture. Confirmatory laboratory testing should be done through the LRN under strict biosafety conditions because of the risk of laboratory transmission.

Tularemia is a zoonotic illness caused by an aerobic gram-negative coccobacillus, *Francisella tularensis*. Pulmonary tularemia has a high mortality rate and, similarly to the agents mentioned, has a rapid onset of symptoms and progression to respiratory failure. Tularemia is not spread from person to person. These organisms require stringent growth conditions and are therefore difficult to isolate in culture. Specimens should be referred to an LRN facility, where a presumptive diagnosis may be made using DFA, PCR, and culture testing; serology is also indicated.

POINTS TO REMEMBER

- The method and site of collection, quality of the clinical specimen, and clinical context are all important factors to consider when distinguishing between colonization and infection.
- The age and immune status of the host will help determine likely infectious pathogens.
- The normal microbiota and specific anatomic structures play a role in defending the host from respiratory tract infection.
- Virulence factors of disease-producing organisms enable them to evade host defense mechanisms, cause clinical infection, and induce tissue disease.
- The prevalence of different viral respiratory pathogens varies according to seasonal changes in epidemiology.
- Newer pathogens such as SARS-CoV, MERS-CoV, SARS-CoV-2 can cause severe and sometimes fatal illness. It is important to be aware of their existence and clinical significance.
- Healthcare-associated pathogens are often resistant to multiple antimicrobial agents, and it is important to have a working knowledge of local antimicrobial resistance patterns.
- The occurrence of opportunistic disease in patients with HIV infection is a function of underlying host immunodeficiency and pathogen virulence.
- Immunocompromised patients, including those who have undergone hematopoietic cell or organ transplantation, are at increased risk for serious pneumonias caused by a wider range of pathogens (opportunistic agents) than that observed with immunocompetent patients.
- Awareness of potential agents of bioterrorism, as listed by the CDC, is important. Consider these uncommon pathogens on the list of possible causes in the differential diagnosis.

LEARNING ASSESSMENT QUESTIONS

1. Why is it important to distinguish between normal microbial biota and pathogenic microorganisms?
2. Why is it important to assess the immune status of the host when determining the importance of a microorganism detected in the diagnostic microbiology laboratory?
3. What is meant by an *opportunistic pathogen*?
4. Why should the microbiologist maintain awareness of seasonal trends in respiratory tract infections? Give examples of infectious agents for which these trends are noted.
5. How does the transmission of SARS-CoV-2 differ from other respiratory viruses?
6. What are common bacterial pathogens that cause CAP?
7. What is the epidemiologic importance of the distinction between antigenic drift and antigenic shift for influenza virus infections?
8. What is the difference between CAP and HAP as related to the likely bacterial pathogens? Why is there a different spectrum of pathogens for these two clinical situations?
9. What is the significance of the absolute CD4 cell count in determining the susceptibility to infection and the likely pathogens in a patient with HIV or AIDS?
10. What diagnosis should be suspected in a patient with a chronic pneumonia who is homeless and presents with a 3- to 4-week history of increasing fatigue, weight loss, and night sweats?
11. Which bacterial pathogens cause pneumonia and are designated as the highest-level threat (category A) potential agents of bioterrorism by the Centers for Disease Control and Prevention (CDC)?
12. What is the difference in laboratory protocol for diagnostic studies that should be considered for all agents of bioterrorism?

13. What should a microbiologist do if he or she finds α -hemolytic colonies on a properly collected sputum specimen for a patient suspected of having lobar pneumonia?
 - a. Ignore the colonies because they are normal microbiota.
 - b. Ignore the colonies because no known pathogens for pneumonia are α -hemolytic.
 - c. Do a full workup to identify the organism.
 - d. Suspect a bioterror agent and send the isolate to a laboratory response network reference laboratory.
14. What is the cause of reduced clearance of respiratory secretions that predisposes people to respiratory infections?
 - a. Obstruction by a foreign body
 - b. Alterations in the viscosity of the mucus
 - c. Immature anatomic development
 - d. All of the above
15. Which organisms are most frequently isolated from middle ear cultures of individuals with otitis media?
 - a. *Staphylococcus aureus* and *Escherichia coli*
 - b. *Streptococcus pneumoniae* and *Haemophilus influenzae*
 - c. *Streptococcus pneumoniae* and *Mycoplasma pneumoniae*
 - d. *Haemophilus influenzae* and *Neisseria meningitidis*
16. Which organism is the most common opportunistic pathogen that routinely infects patients with HIV/AIDS?
 - a. *Pneumocystis jirovecii*
 - b. *Mycoplasma pneumoniae*
 - c. *Serratia marcescens*
 - d. Respiratory syncytial virus
17. A 3-month-old infant presented with persistent symptoms that include paroxysmal cough, breathing difficulty, fever, and vomiting after a spasm of coughing. Cyanosis and intercostal retractions were noted. The infant also had a fever. Nasopharyngeal secretions were collected and analyzed. The organism was biochemically inert. Based on these clinical findings, what is the most likely suspected agent?
 - a. *Mycoplasma pneumoniae*
 - b. *Pneumocystis jirovecii*
 - c. *Bordetella pertussis*
 - d. Respiratory syncytial virus
18. A 25-year-old previously healthy female patient presented with sore throat, earache, and nonproductive cough of several days' duration. She had a low-grade fever and malaise, and although she did not feel completely well, she did not feel sick enough to stay in bed. Testing showed a normal white blood cell count with routine bacterial sputum culture negative for typical pathogens, but x-ray examination revealed pulmonary infiltrates. Based on these clinical findings, what is the most likely suspected agent?
 - a. *Mycoplasma pneumoniae*
 - b. *Pneumocystis jirovecii*
 - c. *Bordetella pertussis*
 - d. *Streptococcus pneumoniae*
19. A 67-year-old male patient who smokes 15 to 20 cigarettes per day presented with a persistent cough, malaise, and a fever of 102° to 105°F. On admission, the patient was disoriented and complained of nausea and vomiting. Repeat sputum cultures yielded only normal respiratory tract biota, although a direct Gram-stained smear showed 3+ PMNs and rare epithelial cells. Based on these clinical findings, what is the most likely suspected agent?
 - a. *Mycoplasma pneumoniae*
 - b. *Pneumocystis jirovecii*
 - c. *Legionella pneumophila*
 - d. *Streptococcus pneumoniae*
20. You received a sputum sample from a patient with history of chronic obstructive pulmonary disease. On admission, the direct Gram-stained smear showed gram-positive diplococci, more than 10 squamous epithelial cells per low-power field, and less than 25 polymorphonuclear cells per low-power field. Which of the following would be your interpretation of the direct Gram-stained smear?
 - a. The sample is acceptable for culture.
 - b. The sample is not acceptable for culture.
 - c. The number of squamous epithelial cells present in sputum are acceptable.
 - d. The gram-positive diplococci present are significant if recovered in culture.

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the function of the skin as a host defense mechanism.
2. Identify the organisms that constitute normal skin biota.
3. Contrast the clinical presentations and the most common causative agents of each of the following types of skin infections: dermatitis, folliculitis, furuncle, carbuncle, impetigo, erysipelas, and cellulitis.
4. Differentiate risk factors, causative agents, and clinical manifestations of the following soft tissue infections: diabetic foot infections, infectious gangrene, mycetoma, and nodular lymphangitis.
5. Recognize the dermatologic manifestations of systemic bacterial infections.
6. Compare the dermatologic manifestations of fungal infections including systemic candidiasis.
7. Identify the etiologies and describe the manifestations of the common childhood viral exanthems.
8. Describe the pathogenesis of herpesvirus skin diseases.
9. Categorize the most frequent parasitic causes of cutaneous infection and describe their typical appearances.
10. Describe the characteristics and usual causative agents associated with disseminated intravascular coagulation, vasculitis, toxic shock syndrome, scarlet fever, and immune complex and embolic disease.
11. Evaluate the strengths and weaknesses of the common laboratory methods for diagnosing skin infections.

Case in point

A 60-year-old male patient with poorly controlled type 2 diabetes presented to the emergency department with high-grade fever, chills, and severe pain and swelling in his right foot and lower leg. Two days before admission, he was working outside his home and scraped his lower leg against a brick wall. This area became red, swollen, and progressively more painful over 48 hours. On physical examination, the patient was febrile (103° F, reference range 97° to 99° F), his blood pressure was low (90/50 mm Hg, reference range 120/80 mm Hg), and the right leg and foot were red, swollen, and markedly tender, with several purple bullae starting to develop. His white blood cell count was elevated ($22 \times 10^9/L$, reference range 4.5 to $11 \times 10^9/L$). Blood cultures were obtained, and intravenous antimicrobial therapy was started. A computed tomography scan of the leg showed gas formation in the subcutaneous tissues. The patient was taken to surgery and found to have necrosis of the subcutaneous tissues down to the fascia, with purulent material present. The area was extensively debrided, and tissue and pus were sent to the laboratory for Gram stain and culture. These specimens grew multiple organisms, including *Escherichia coli*, *Bacteroides* sp., and *Peptostreptococcus* sp. The blood cultures also grew *E. coli*. After several additional debridements, a long hospitalization, and skin grafting, the patient fully recovered.

Issues to consider

After reading the patient's case history, consider:

- The clinical clues (e.g., patient characteristics, information obtained from the history and physical examination) used by the health care provider to diagnosis the patient's illness
- The specimen collection procedures appropriate to maximize recovery of the infectious agents
- The sample processing that should occur once the specimen arrives in the laboratory
- The types of organisms likely to be recovered on culture based on the site of infection and the events leading to the infection

The skin is the body's first line of defense against invasion by pathogens or by bacteria and fungi that inhabit the skin surface. As a dynamic physical barrier, the skin continually undergoes epithelial cell turnover, removing substances as well as potentially pathogenic microorganisms on its surface. In addition, the skin is colonized with a variety of resident microbes that perform a protective function.

This chapter discusses the following:

- The role of indigenous skin biota and other organisms in the pathogenesis of skin infection
- The clinical features and causes of various primary skin and soft tissue infections
- The dermatologic manifestations of systemic infections
- The diagnosis and treatment of specific types of skin and soft tissue infections

Anatomy of the skin

The skin consists of three layers: the epidermis, dermis, and subcutaneous layer (Fig. 33.1). The epidermis is the outermost layer and is composed of several layers of epithelial cells. The stratum corneum, the outermost layer of the epidermis, contains dead cells consisting of a protein called *keratin*. The second skin layer, the dermis, is a thick layer composed of connective tissue. Sweat gland ducts, hair follicles, and oil gland ducts are found in the dermis and penetrate the subcutaneous layer. These structures also provide potential passageways through which microbes can enter the skin. Sebum and perspiration provide moisture and nutrients necessary for the growth of certain microbes. Salt and lysozymes contained in perspiration and fatty acids found in sebum can inhibit the proliferation of some pathogenic microorganisms.

Skin microbiota

Even though it is not a particularly inviting habitat for microbes, the skin is continually exposed to the environment and is inhabited by millions of microorganisms. The usual biota of the skin can adapt to its high salt concentration, exposure to the elements, and relative lack of nutrients and moisture. The normal resident skin microbiota is made up of an array of bacteria, fungi, and viruses that are adjacent to the epidermis but can also be in the dermal tissues. The organisms can act as competitive inhibitors of pathogens but breaks in the skin may allow normal biota to cause infection and permit more transient organisms to enter and cause disease.

Variations in the skin microbiota from person to person are based on a number of factors such as gender, age, geography, hygiene, and the presence of skin or other diseases. Skin biota also vary in body location depending on changes in temperature, moisture, and concentration of sebaceous or sweat glands. However, important members include gram-positive cocci, particularly staphylococci and streptococci; coagulase-negative staphylococci such as *Staphylococcus epidermidis* are permanent skin residents, while coagulase-positive *Staphylococcus aureus* is a transient colonizer. Other members of the normal biota include the gram-positive bacilli *Cutibacterium acnes* and *Corynebacterium* and yeasts *Candida* and *Malassezia*. These resident organisms may become pathogens if there is trauma to the skin. Although vigorous washing reduces the amount of surface skin biota, it does not eliminate resident microbiota **colonization**. The acidic pH of skin (~5) inhibits many common skin pathogens.

Fig. 33.1 Anatomy of the skin. (From Patton, K. T., & Thibodeau G. A. [2019]. *Anatomy and physiology* [10th ed.]. St Louis: Elsevier.)

Localized bacterial and fungal skin infections

An extensive list of infections can involve the skin (Box 33.1). Bacteria cause the most skin infections, and they have become more difficult to treat because of increasing antimicrobial resistance. Table 33.1 shows the results of a survey of the causative agents of skin and soft tissue infections isolated from patients in North America between 1998 and 2004. *S. aureus*, an organism that is resistant to many common antimicrobials, was the predominant skin and soft tissue pathogen, accounting for almost 45% of over 5800 isolates. *Pseudomonas aeruginosa*, another microorganism that displays multidrug resistance, ranked a distant second at 11%.

Skin and soft tissue infections may be classified in multiple ways. One method classifies them based on the appearance of the skin lesion, which provides an important clue about possible causative organisms, as noted in Box 33.1. Skin and soft tissue infections also may be classified, as they are in this chapter, according to whether they occur as a manifestation of systemic disease or as a primary skin process. Primary skin infections can then be classified by the skin and soft tissue structure affected, and further subdivided by causative organism (e.g., bacterial, viral, mycobacterial, fungal, parasitic). It is also notable that a variety of the pathogens described in this chapter may cause infection as a secondary process, gaining

access to the skin after it is disrupted as a result of another preexisting skin condition (Table 33.2).

The first section of this chapter examines the clinically important and prevalent infections of skin and soft tissues that typically occur in localized areas of the body. They are presented in order from the most superficial infections to the deeper, more serious infections. They are predominantly the result of bacterial and fungal infection. Additional sections describe skin manifestations of systemic infections caused by bacteria, fungi, viruses, and parasites, including immune- or toxin-mediated dermatologic diseases triggered by pathogens.

Dermatitis

Dermatitis is a general term that describes an inflammation of the skin. It is characterized by areas of redness, swelling, and sometimes scaling of the skin and/or pruritus. There are many causes, only some of which are related to infection. The following section focuses on the most common infectious causes of dermatitis.

Intertrigo and superficial candidiasis

Intertrigo (intertriginous dermatitis) is an inflammatory cutaneous condition that occurs in body areas subjected to heat, moisture, and friction, which work together to cause skin breakdown. Infectious agents enhance this process.

Table 33.1 Order of bacteria causing skin and soft tissue infections in North America, 1998 to 2004

Rank	Pathogen	No. of isolates (% of total)
1	<i>Staphylococcus aureus</i>	2602 (44.6)
2	<i>Pseudomonas aeruginosa</i>	648 (11.1)
3	<i>Enterococcus</i> spp.	542 (9.3)
4	<i>Escherichia coli</i>	422 (7.2)
5	<i>Enterobacter</i> spp.	282 (4.8)
6	<i>Klebsiella</i> spp.	248 (4.2)
7	β -Hemolytic streptococci	237 (4.1)
8	<i>Proteus mirabilis</i>	166 (2.8)
9	Coagulase-negative staphylococci	161 (2.8)
10	<i>Serratia</i> spp.	125 (2.1)

From Moet, G. J., et al. (2007). Contemporary causes of skin and soft tissue infections in North America, Latin America, and Europe: report from the SENTRY Antimicrobial Surveillance Program (1998–2004). *Diagnostic Microbiology and Infectious Disease*, 57, 7.

Intertrigo usually occurs in the skin folds, typically the axillae, perineum, beneath the breasts, and in abdominal folds. Risk factors include obesity, incontinence, diabetes, compromised immunity, and extremes of age (e.g., diaper rash in infants). The most common organism present in these areas is *Candida*, although *S. aureus* and Enterobacterales also can play a role.

Intertrigo is one form of superficial candidiasis, but *Candida* can affect the skin and mucous membranes in other forms. Thrush is a type of candidiasis involving the oral mucosa characterized by white, curdlike patches on the tongue, palate, or buccal mucosa. These patches adhere to the mucosa but can be removed by scraping, leaving a raw, erythematous base. A similar process can occur in the vulvovaginal area, leading to *Candida* vaginitis. Balanitis, an inflammation of the glans penis that can spread to the thighs, scrotum, and buttocks, is commonly caused by *Candida* as well. Thrush and *Candida* vaginitis can be the result of antimicrobial use or immunocompromised state (e.g., due to human immunodeficiency infection or corticosteroid use). The balance of the normal microbiota can be altered by antimicrobial agents or immunosuppression and allow an overgrowth of yeast that

Table 33.2 Infections secondary to preexisting skin lesions

Infection	Major pathogen
Surgical wound infection	
Clean	<i>Staphylococcus aureus</i> , gram-negative bacilli
Contaminated, such as colon	<i>S. aureus</i> , streptococci, Enterobacterales, anaerobes
Intravenous catheter or percutaneous drain sites	<i>S. aureus</i> , coagulase-negative staphylococci, streptococci
Trauma	
Soil contamination	<i>Pseudomonas aeruginosa</i> , <i>Clostridium</i> spp., <i>Nocardia</i> spp., fungi
Freshwater contamination	<i>Aeromonas</i> , <i>Plesiomonas</i> , <i>Mycobacterium marinum</i>
Saltwater contamination	<i>Vibrio vulnificus</i> , <i>M. marinum</i>
Intravenous drug use	<i>S. aureus</i> , <i>Pseudomonas</i> spp., <i>Clostridium</i> spp.
Bites	
Human	Oral aerobes and anaerobes, <i>S. aureus</i>
Dog, cat	<i>Pasteurella multocida</i> , <i>S. aureus</i> , <i>Capnocytophaga canimorsus</i> , anaerobes
Rat	<i>Streptobacillus moniliformis</i> , <i>Spirillum minus</i>
Arthropod	<i>Yersinia pestis</i>
Other	
Decubitus ulcer	Streptococci, <i>S. aureus</i> , Enterobacterales, <i>Pseudomonas</i> spp., anaerobes, including <i>Bacteroides fragilis</i>
Foot ulcer in diabetic patients	<i>S. aureus</i> , streptococci, Enterobacterales, <i>P. aeruginosa</i> , anaerobes
Hidradenitis suppurativa	<i>S. aureus</i> , streptococci, Enterobacterales, <i>Pseudomonas</i> spp., anaerobes
Burns	<i>S. aureus</i> , <i>Candida</i> , <i>P. aeruginosa</i>

is normally present on skin or mucosal surfaces. *Candida* can also cause paronychia, an inflammation of the folds of the skin bordering the nail beds (see later), or onychomycosis, an infection of the nail itself.

Superficial forms of candidiasis are often treated successfully with topical antifungal agents such as nystatin or clotrimazole. Oral antifungal agents such as fluconazole, itraconazole, or voriconazole may be necessary for the treatment of more severe infections, particularly in those who are immunocompromised.

Erythrasma

Erythrasma is a superficial, chronic skin infection that manifests as pruritic, reddish-brown macules that are lightly scaled and wrinkled. The lesions are usually found in intertriginous areas, especially the groin, inner thighs, and toe webs. Axillae, intergluteal folds, and inframammary regions

are less often affected. The infection occurs more often in men, obese individuals, and patients with diabetes and is generally localized and benign but can become widespread in those with an impaired immune system. *Corynebacterium minutissimum*, a normal skin biota resident, is the causative organism and can be observed as filamentous rods with a Gram stain of samples taken from the stratum corneum. The lesions also produce a coral red fluorescence when examined under a Wood lamp. Topically administered erythromycin or clindamycin or orally administered erythromycin or clarithromycin are useful in the management of erythrasma. Topical 2% mupirocin has also shown efficacy in recent reports.

Dermatophytoses

For most dermatophytoses, humans are the primary reservoir. Occasionally, infections are acquired from infected domestic animals or soil. Dermatophytes are molds that colonize only keratinized surfaces of the body, including hair, nails, and skin. These organisms can invade the stratum corneum of the skin, causing superficial infection in various regions of the body; the feet, groin, scalp, and nails are affected most often. Dermatophytes within four genera (*Trichophyton*, *Epidermophyton*, *Nannizzia*, and *Microsporum*) generally cause infection. The mode of transmission is through direct skin-to-skin contact or indirect contact via contaminated fomites or environmental surfaces. However, it seems that all persons are not equally susceptible to infection.

The classic lesion of a dermatophyte infection is a circular scaly patch of erythema with a raised border (Fig. 33.2). The edges are often more inflamed than the center. These infections are also known as *ringworm*, reflecting the tendency of some lesions to expand in a circular fashion. The term **tinea**, used to denote a dermatophyte infection, is attached to a descriptor of the site of infection. For example, tinea cruris (jock itch) is a dermatophyte infection of the groin and perianal region, tinea pedis (athlete's foot) involves the feet, and tinea capitis is infection of the scalp (Fig. 33.3). In addition to *Candida*, dermatophytes are another cause of onychomycosis. *Tinea unguium* is the term used for this infection, which can result in significant thickening and discoloration of the nails. Tinea corporis (see Fig. 33.2) is a dermatophyte infection of the body in general, and often involves the trunk and legs.

The diagnosis of dermatophytosis and the identification of its causative agents can generally be accomplished by taking scrapings of lesions, softening the material in a 10% to 20% potassium hydroxide solution, and then examining the specimens microscopically for fungal hyphae. Calcofluor is useful to stain hyphae but requires the use of a fluorescent microscope. Skin or nails can be scraped with a scalpel blade, or nails can be clipped to obtain material for identification. Scrapings can also be observed under a Wood lamp, where certain dermatophytes (*Microsporum*) will fluoresce yellow-green. The precise mycologic cause can be confirmed by culturing infected material on Sabouraud dextrose agar (SDA). Dermatophytosis can be treated with a wide variety of topical antifungal agents, most commonly azole medications such as miconazole, clotrimazole, or econazole. Nail infections often require oral systemic antifungal therapy for treatment (e.g., terbinafine, itraconazole, or fluconazole).

Fig. 33.2 Tinea corporis.

Fig. 33.3 Tinea capitis.

Tinea versicolor

Tinea versicolor, or pityriasis versicolor (Fig. 33.4), is an extremely common dermatitis that occurs worldwide. Unlike the tinea infections described earlier, tinea versicolor is not caused by a dermatophyte but by normal skin commensals. The lipophilic *Malassezia* spp. (*Malassezia globosa*, *M. sympodialis*, *M. furfur*) and other *Malassezia* spp. cause tinea versicolor. The characteristic skin manifestation of tinea versicolor is a diffuse distribution of hypopigmented or, less commonly, hyperpigmented macules, principally located on the trunk and proximal portions of the extremities. The lesions are usually nonpruritic and often coalesce to form scaly plaques.

The clinical features suggest the diagnosis, but it is recommended to confirm with a potassium hydroxide preparation

of skin scrapings because dermatophyte infections or *Candida* dermatitis could appear similar. *Malassezia* will display a “spaghetti and meatballs” appearance under the microscope, with round yeast forms and filamentous hyphae (see Chapter 27, Fig. 27.11). Spontaneous remission may occur in some patients; for others, topically administered azoles (e.g., ketoconazole) or topical terbinafine are effective. Selenium sulfide lotion can also be used.

Pyoderma

The **primary pyodermas** are a group of inflammatory skin disorders caused by bacteria that produce pus. The terms *impetigo* and *pyoderma* have been used interchangeably by some authors and in clinical practice, but there are other forms of pyoderma (see later), as listed in Table 33.3.

Impetigo

Impetigo is a common pyoderma that is most often seen in children (Fig. 33.5). Historically, most cases were caused by group A streptococci (GAS; *Streptococcus pyogenes*), although *S. aureus* has become the predominant pathogen over the past 20 years. The frequency of **methicillin-resistant *Staphylococcus aureus*** (MRSA) varies depending on the population studied and the presence of overcrowded living conditions or underlying diseases like diabetes mellitus. Group B *Streptococcus* occasionally causes impetigo in newborns secondary to the acquisition of colonizing vaginal microbiota from the mother. Impetigo is common in hot and humid climates and is highly contagious, particularly in households with poor hygiene. Initially, the lesions of impetigo begin as small **vesicles** that become pustules that rupture. The discharge is thick and yellow and dries to form the classic golden crusts. The lesions are superficial and painless and do not scar. They can be pruritic and are easily spread by scratching.

The bullous form of impetigo is much less common. It is caused by strains of *S. aureus* that produce exfoliative toxins leading to the formation of **bullae** that quickly rupture and form a transparent, light brown crust. The diagnosis of impetigo can be made from a Gram-stained smear and culture of the vesicular contents, and it is important to distinguish the lesions from herpes simplex virus (HSV), which can also cause vesicular or crusted skin lesions (see the “Herpes Simplex Viral Infection” section later in this chapter).

Orally administered penicillin is efficacious for streptococcal impetigo, but because many cases involve *S. aureus*, penicillinase-resistant oral penicillins such as dicloxacillin or an antistaphylococcal cephalosporin such as cephalexin are better options for empiric treatment. If the patient is allergic to penicillin, clarithromycin or erythromycin may be used. Because of the possibility of community-acquired MRSA infection (CA-MRSA; see the “Cellulitis” section later in this chapter), antimicrobials with activity against these organisms, such as doxycycline, clindamycin, or trimethoprim-sulfamethoxazole, may be preferable if a significant level of CA-MRSA is circulating in the community or if there is inadequate response to narrower-spectrum agents. If the infection is mild and the lesions are not numerous, topical rather than oral antimicrobial agents should be used, including 2% mupirocin or retapamulin. Mupirocin, unlike

Fig. 33.4 Hypopigmented (A) and hyperpigmented (B) rash of tinea versicolor.

Table 33.3 Common primary pyodermas		
Infection	Organism	Features
Impetigo	<i>Staphylococcus aureus</i> , <i>Streptococcus pyogenes</i>	Children affected most; communicable; no fever
Erysipelas	<i>S. pyogenes</i> ; occasionally other β -hemolytic streptococci or <i>S. aureus</i>	Distinct raised borders; fever common
Cellulitis	<i>S. pyogenes</i> , <i>S. aureus</i> ; <i>Haemophilus influenzae</i> in children	Erythema, tenderness, pain, edema, warmth; fever common
Folliculitis	<i>S. aureus</i> ; gram-negative bacilli or <i>Candida</i> if predisposing conditions, <i>Malassezia</i> spp.	Papules around hair follicles; areas exposed to whirlpool bath (<i>Pseudomonas aeruginosa</i>)
Furuncle	<i>S. aureus</i>	Fluctuant, painful nodules often in intertriginous areas
Carbuncle	<i>S. aureus</i>	Multiple abscesses
Paronychia	<i>S. aureus</i> , <i>S. pyogenes</i> , gram-negative bacilli, <i>Candida</i>	Periungual swelling

Fig. 33.5 Bullous impetigo caused by *Staphylococcus aureus*.

retapamulin, is approved for topical treatment of MRSA, although resistance to mupirocin among MRSA strains has been increasing.

Erysipelas

Erysipelas is a type of superficial skin infection that involves not only the epidermis but also the underlying dermis and lymphatic system. Erysipelas is usually seen in children and older adults and is sometimes preceded by a respiratory β -hemolytic streptococcal infection. In the past, the infection

typically occurred on the face (Fig. 33.6), but now it is much more frequently seen in the lower extremities. Predisposing factors in adults include diabetes mellitus, alcohol abuse, venous stasis, trauma, skin ulcers or chronic inflammatory skin conditions, and lymphatic obstruction.

The lesions of erysipelas are characterized as painful, indurated areas of inflammation with raised borders that are sharply demarcated from the adjacent normal skin. The involved skin usually has a bright red to crimson hue, and patients often have fever. Most uncomplicated cases remain confined to the dermis and lymphatics, but deeper extension with cellulitis (see the “Cellulitis” section), abscess formation, or necrotizing fasciitis may occur, and bacteremia is found in a minority of cases, making erysipelas a potentially life-threatening infection.

Most infections are caused by GAS, with a minority of infections caused by other β -hemolytic streptococci and *S. aureus*. Usually, the diagnosis is based on the clinical presentation because it is difficult to isolate GAS from the skin lesions. On occasion, aspiration of the advancing edge of

Fig. 33.6 Erysipelas caused by *Streptococcus pyogenes*.

a lesion with culture of the aspirate has been successful in identifying the organism. Penicillin is the primary treatment, although first-generation cephalosporins such as cephalexin or erythromycin can be effective therapy.

Erysipeloid

Erysipeloid is a superficial soft tissue infection caused by *Erysipelothrix rhusiopathiae*, a gram-positive rod. It is an occupational hazard of handlers of animals, meat, poultry, hides, and saltwater fish. Because it is typically introduced by trauma, the fingers and dorsum of the hand are the most frequent sites of infection. Mimicking erysipelas, the erysipeloid lesion is red and painful, with raised borders. Septic arthritis and bacteremia may occur as complications. The organism is difficult to see on Gram stain but may be isolated in culture. Penicillin G is the preferred treatment.

Anthrax

Bacillus anthracis, the agent of anthrax, is a gram-positive rod that causes an acute febrile illness with a mortality rate ranging from <2% with cutaneous disease to 45% for pneumonia and 92% for anthrax meningitis. The cutaneous form of anthrax is an ulcerative disease and is more common than pulmonary or systemic infection. The skin lesions typically occur in persons working with infected animals (sheep, goats, cattle, and other herbivores) or animal products such as wool that are contaminated with *B. anthracis* spores. Intravenous (IV) drug use is another mechanism for infection, although anthrax is uncommon in the United States. A bioterrorism-related anthrax outbreak did occur in the United States in 2001 when *B. anthracis* spores were sent by mail to media and congressional offices resulting in 11 cutaneous and 11 pulmonary cases of anthrax and 5 deaths.

Anthrax skin lesions are usually seen on the face, neck, or arms at sites of minor abrasions. They begin as painless papules that vesiculate and are surrounded by significant erythema and a gelatinous type of edema. The vesicle evolves into a hemorrhagic and then necrotic lesion, and an eschar forms, although the skin lesions remain painless. Regional lymphadenopathy can be present, and bacteremia may occur with fever and hypotension. The diagnosis is often suspected

clinically given the characteristic skin lesions, but biopsy and culture should be performed for confirmation. The finding of *B. anthracis* from a clinical specimen constitutes a critical value and should be communicated to the patient's health care provider immediately.

Penicillin has long been the drug of choice for the treatment of anthrax, but with the bioterrorism cases that occurred in the United States, concerns have arisen that strains can be deliberately altered so they are resistant to commonly used antimicrobial agents. Therefore treatment with ciprofloxacin or doxycycline has been recommended as initial therapy. Anthrax vaccine is licensed for preexposure prophylaxis for adults at high risk for exposure to *B. anthracis* and, in combination with antibiotics, for adults with suspected or known exposure to aerosolized *B. anthracis* spores.

Cellulitis

Cellulitis is a diffuse inflammation and infection of the superficial skin layers and subcutaneous tissues. It is a very common form of skin and soft tissue infection that accounts for many hospitalizations and physician visits each year. Cellulitis extends deeper in the soft tissues than erysipelas and appears as an area of painful erythema, warmth, and edema of the skin, with poorly defined margins. Drainage of pus from areas of cellulitis may occur (purulent cellulitis), and these cases are usually caused by *S. aureus*. Depending on its extent and severity, cellulitis may or may not be accompanied by fever and other clinical or laboratory features of systemic infection (e.g., malaise, rigors, headache, elevated white blood cell count). Predisposing factors include surgery or other trauma and underlying skin disorders, such as ulcers or dermatitis.

Blood cultures are usually negative, and the diagnosis is often made clinically, based on the appearance of the affected area. In some cases, such as in immunocompromised patients or those who are not responding to empiric antimicrobial therapy, it may be useful to perform needle aspiration at the leading edge of an area of cellulitis for aerobic and anaerobic culture. Rates of organism recovery with this procedure have ranged in studies from 0% to 40%. The most common causative agents are GAS and *S. aureus*, although group B, C, and G streptococci can also cause cellulitis. Intravenous or oral systemic antimicrobial agents directed at *S. aureus* and streptococci are generally effective treatment for cellulitis. Patients who experience trauma or who have chronic open wounds, such as diabetic patients with foot ulcers, may develop surrounding cellulitis caused by a mixture of gram-positive and gram-negative organisms, including anaerobes (see later), and may require broader antimicrobial therapy.

Recurrent cellulitis

Lymphedema, obesity, venous stasis, and untreated tinea pedis are associated with an increased risk of developing recurrent skin and soft tissue infections. Breaks in skin integrity can allow the development of infection, and impaired lymphatic drainage can impede host immune responses and clearance of pathogens. In addition, bouts of infection can lead to scarring and further chronic edema. Patients with frequent cellulitis recurrences may be treated with long-term antimicrobial regimens in an attempt to decrease the rate of infection.

Methicillin-resistant *Staphylococcus aureus* infections

S. aureus is the most common cause of skin and soft tissue infections in the United States. Approximately 20% of individuals persistently carry *S. aureus* in the nares, and another 30% carry the organism intermittently. This carriage increases the risk that an individual will develop staphylococcal infection. *S. aureus* has acquired resistance to a variety of antimicrobials, and MRSA accounts for many cases of skin and soft tissue infection. MRSA infections are associated with higher mortality rates and greater health care costs compared with those caused by methicillin-susceptible *S. aureus*.

MRSA is prevalent in the hospital setting, where 25% to 50% of *S. aureus* isolates are methicillin resistant; the proportion is usually higher in intensive care units. However, MRSA has also increased in frequency in the community since the 1980s among persons with no prior exposure to hospitals, nursing homes, dialysis centers, or other health care settings. Investigations of CA-MRSA cases have shown that children, incarcerated persons, military personnel, athletes involved in contact sports, IV drug users, household contacts of persons with CA-MRSA infection, men who have sex with men, and Native Americans are at increased risk for infection by CA-MRSA. The extensive use of antimicrobials in livestock has also led to widespread carriage of MRSA in animals, and this can be a source of infection for humans. Several different strains of CA-MRSA are known, but strain USA300 is the most prevalent and has been associated with more severe disease, including bacteremia, necrotizing pneumonia, and severe soft tissue infection. Of note, this strain has also become prevalent in health care institutions. Although the incidence of hospital-onset MRSA infections has decreased, likely because of efforts in reducing healthcare-associated infections, progress against MRSA has seemed to stall since 2013.

MRSA infections are generally treated with intravenously administered vancomycin, although CA-MRSA isolates are typically resistant to fewer non- β -lactam antibiotics, and agents such as clindamycin, trimethoprim-sulfamethoxazole, and tetracyclines may be effective. Attempts at eliminating MRSA colonization of the body may also be helpful in preventing acquisition of infection in the hospital (e.g., at the time of surgery) or in preventing recurrent infection. Decolonization involves applying mupirocin to the nares (where MRSA is often carried) and washing with a skin antiseptic such as chlorhexidine or dilute bleach baths for 5 to 10 days. Hand hygiene, carefully cleaning surfaces that are frequently touched, avoiding sharing of personal items such as towels and razors, and keeping infected wounds covered are important for preventing the spread of MRSA. However, MRSA infections may recur despite preventive measures.

Paronychia

Paronychia is an infection of the cuticle surrounding the nail bed. Cases generally follow minor trauma, such as removing a hangnail. The involved part of the finger at the nail margin becomes painful, red, warm, and swollen, and pus may be expressed from around the nail bed. *Candida*, staphylococci, or streptococci are the usual causative organisms. Paronychia usually responds to warm soaks, which often lead to spontaneous drainage of pus and resolution. Systemic antimicrobial therapy and surgery may be needed in unusual cases.

Folliculitis

Folliculitis is an inflammation and infection of hair follicles. *S. aureus* is the most common causative agent of folliculitis, although *P. aeruginosa* has been implicated in cases acquired from contaminated swimming pools or hot tubs. In immunocompromised hosts, *Candida* spp., *Malassezia* spp., or gram-negative bacteria may cause folliculitis. Lesions appear as small, erythematous papules that may be pruritic, and they often evolve to form pustules with a whitish or yellowish central zone. Sycosis barbae is a form of folliculitis occurring in bearded areas of the face. The differential diagnosis of these folliculitis syndromes includes conditions that have a non-infectious etiology such as eosinophilic pustular folliculitis, seen in persons with acquired immunodeficiency syndrome (AIDS), or the folliculitis that is an adverse effect from certain targeted cancer immunotherapy agents.

Furuncles and carbuncles

Folliculitis can sometimes progress to form deeper inflammatory nodules called **furuncles** (Fig. 33.7), especially in warm, moist areas of the body and areas subjected to friction. Certain individuals are predisposed to the development of furuncles, including those with diabetes mellitus, obesity, or defects in immune function. Furuncles are initially red and firm but soon become painful and fluctuant and generally drain spontaneously. *S. aureus* is the most common causative pathogen. Furuncles usually can be managed by the application of moist heat to accelerate drainage, although systemic antimicrobial therapy may be needed depending on the severity.

A **carbuncle** is a more serious lesion that extends into the subcutaneous fat. It consists of multiple coalescing abscesses that can drain at several adjacent sites along hair follicles. Carbuncles commonly occur at the nape of the neck and on the back of the thighs and are often associated with fever and other systemic symptoms. Bacteremia can be a complicating event, and surgical drainage is needed for most carbuncles. Purulent drainage should be cultured to confirm the organism, which is typically *S. aureus*. As noted previously, because CA-MRSA has become a prevalent cause of skin and soft tissue infections, furuncles and carbuncles that are significant should be treated empirically with antimicrobial agents that have activity against MRSA. For milder infections, trimethoprim-sulfamethoxazole or tetracyclines can be used, and agents such as vancomycin, linezolid, or daptomycin are recommended for severe infections. If methicillin-susceptible *S. aureus* is cultured, dicloxacillin or cephalixin is effective.

S. aureus isolates exhibiting less susceptibility to vancomycin, known as *vancomycin intermediate-resistant S. aureus* (VISA), were discovered in the 1990s, and infections by VISA have been accompanied by failure of vancomycin therapy and poor outcomes. *S. aureus* isolates with complete resistance to vancomycin were first reported in the United States in 2002. However, resistance to vancomycin among *S. aureus* remains very rare in the United States despite its widespread use.

Hidradenitis suppurativa

Hidradenitis suppurativa is a difficult-to-treat, recurrent infection of the apocrine sweat glands. For unclear reasons, chronic obstruction of these glands, particularly in the axillae and groin, occurs in certain individuals, which predisposes

Fig. 33.7 *Staphylococcus aureus* furuncle of the breast.

to a secondary mixed bacterial infection of the skin and skin structures. Organisms such as staphylococci, streptococci, gram-negative bacteria (e.g., *E. coli* and *Pseudomonas*), and anaerobic bacteria are commonly involved. The disease manifests as nodular, tender, erythematous swellings that become fluctuant and drain, often associated with fever and tender lymphadenitis. Resolution of the lesions is typically accompanied by scarring of the involved areas. Individual episodes of infection are treated with local moist heat, broad-spectrum antimicrobial agents based on culture results, and frequently with surgical incision and drainage. Multiple recurrences of infection are often seen, which can lead to tissue fibrosis, sinus tract formation, and disfigurement.

Other soft tissue infections

Bite infections

Bites from humans or animals are often complicated by soft tissue infection that can be quite severe. Infections in this setting are generally polymicrobial, caused by a mixture of aerobic and anaerobic organisms found in the mouth of an animal or human inflicting the bite and/or human skin biota. Common pathogens implicated in human bite infections include *Streptococcus anginosus* group, *S. aureus*, *Eikenella corrodens*, *Fusobacterium nucleatum*, and *Prevotella melaninogenica*. Dog and cat bites account for about 1% of U.S. emergency department visits each year, with most caused by dog bites. The incidence of infection after a dog bite injury is between 2 and 25%. *Pasteurella*, *Bacteroides* spp., *Fusobacterium*, *Prevotella*, staphylococci, and *Capnocytophaga canimorsus* are common pathogens following dog bites. *C. canimorsus* may cause a severe sepsis syndrome in patients with liver disease or in those who are asplenic and can lead to **purpura fulminans**, similar to meningococcemia (see the “Immune-Mediated Cutaneous Disease” section later in this chapter).

Cat teeth can inflict very deep wounds that are difficult to irrigate and have a greater risk of infection, soft tissue abscess formation, and infection of underlying bones and joints compared with dog bites. It is estimated that 30% to 50% of cat bites result in infection, and cat bites progress to infection more rapidly than dog bites. Pathogens isolated after cat bites include *Pasteurella multocida*, *Bacteroides* spp., *Fusobacterium*,

Porphyromonas, and staphylococci. The cellulitis associated with bites can spread rapidly and leave permanent disability, particularly when the hand is involved.

Human bites are less common than animal bites and are most often seen in young children. Infections complicate 2% to 25% of human bites. For any bite wounds, wound care, including debridement, culture of deep tissue or purulent drainage, and prompt antimicrobial administration are important. Administration of antimicrobial agents at the time of the bite for 3 to 5 days is recommended to prevent infection in patients who have compromised immune systems or liver disease, or those with deep or severe injuries, particularly to the hand or face. Antimicrobial agents with aerobic and anaerobic activity are indicated for preemptive treatment or therapy of an established bite infection; amoxicillin-clavulanic acid, ampicillin-sulbactam, doxycycline, or a combination of a fluoroquinolone or trimethoprim-sulfamethoxazole with metronidazole are suitable regimens.

Diabetic foot infections

Foot infections are a very common occurrence in persons with diabetes mellitus; they account for a significant amount of morbidity. Risk factors for foot infection include the presence of peripheral neuropathy, trauma to the feet, inadequate blood glucose control, compromise of the peripheral vascular circulation caused by diabetes, impaired kidney function, and improper foot care, including walking barefoot. Manifestations that can occur include cellulitis, typically caused by streptococci or staphylococci (see the “Cellulitis” section earlier in this chapter); acute or chronic soft tissue ulceration, with or without underlying bone infection; and necrotizing infection or gangrene. Ulcerative lesions and gangrene may, like cellulitis, be the result of staphylococcal and streptococcal infection but often are mixed infections and include Enterobacteriales, *Pseudomonas*, gram-positive bacteria, and anaerobic bacteria. The impairment of host defenses seen in diabetic patients can also allow weakly virulent organisms, such as coagulase-negative staphylococci and diphtheroids, to be pathogens in the skin.

Cultures of open wounds are most helpful when they are obtained from deep tissues or from collections of pus beneath the skin surface. Superficial swabs yield little information because diabetic foot ulcers are often colonized with multiple bacteria, which may not necessarily be the agents causing infection. Cellulitis can be treated empirically with antimicrobial agents active against staphylococci and streptococci, whereas foot ulcers should generally be treated empirically with agents that also have gram-negative and anaerobic activity. Definitive antimicrobial therapy should be based on culture results from a deep specimen. Most diabetic foot wounds require debridement and may even result in amputation if blood flow to the area is poor and/or a non-response to wound care and antimicrobial therapy is seen. It is recommended that patients with diabetic foot infections have x-rays or magnetic resonance imaging of the affected area to assess whether there is infection of the bone, soft tissue gas (which signifies a necrotizing infection; see Fig. 33.8), or foreign bodies, and the affected leg should be assessed for adequacy of blood flow.

Fig. 33.8 Diabetic foot infection with soft tissue gas formation.

Case check 33.1

Patients with diabetes mellitus are at high risk for skin and soft tissue infections. Elevated blood glucose levels can impair the body's immune function and make it more difficult to recover from infections. The diabetic patient in the Case in Point developed a polymicrobial infection of the subcutaneous tissue that gave rise to gram-negative sepsis.

Necrotizing soft tissue infection

Infections that produce tissue necrosis and soft tissue gas represent an important subset of skin and soft tissue infection cases. Rapidly progressing and frequently life-threatening, these soft tissue infections can be classified according to their level of soft tissue involvement (e.g., superficial, epidermal, or dermal structures; fascia; muscle) and according to the causative microbiologic agent or agents. Subtypes of necrotizing infection (infectious gangrene) include polymicrobial **necrotizing fasciitis**, typically caused by Enterobacteriales and anaerobes (type I); monomicrobial necrotizing fasciitis, usually caused by *S. pyogenes*; or less commonly, *S. aureus* (type II) and **gas gangrene** (type III, also known as *clostridial myonecrosis*) caused by *Clostridium* spp., usually *Clostridium perfringens* (Fig. 33.9). *Vibrio vulnificus* and *Aeromonas hydrophila* are additional causes of necrotizing soft tissue infection. *Vibrio* infection can occur through contamination of a traumatic injury with seawater or through consumption of raw oysters, and *Aeromonas* infection can occur via medicinal leech therapy or through freshwater contamination of an injury.

Necrotizing soft tissue infections often begin at a site of trauma but may also occur without any obvious portal of entry or as the result of a bacteremia with secondary involvement of the skin and soft tissues. The most common form of necrotizing soft tissue infection is type I, which tends to occur in the trunk and perineal region of patients who have underlying medical illnesses such as diabetes, are immunocompromised, or have had surgery. Genital or perineal necrotizing infection is known as *Fournier's gangrene*. Patients with type II infection can be younger and previously healthy, and infections more often involve the extremities. Blunt trauma, surgery, childbirth, and IV drug use are risk factors for type II infection. Risk factors for necrotizing infection caused by MRSA include IV drug use, diabetes, human immunodeficiency virus (HIV) infection, and malignancy.
